of the Lahey Clinic
Who have contributed much to this book
through the stimulus of their industry,
knowledge and inquiring minds*

PREFACE

THE PURPOSE of this Atlas is to picture in detail the methods and steps of surgical maneuver which have evolved from the work of numerous neurosurgeons. Precise indications for surgical treatment must be determined by accepted methods of investigation and sound clinical judgment. An atlas cannot depict differential diagnosis, but it can describe techniques, and every effort is made to portray the various neurosurgical procedures accurately.

Few modern operative techniques are entirely original; most represent a composite of maneuvers developed over the years. This book cannot attempt to cite the work of the many neurosurgeons, some known and some obscure, who have contributed to the development of modern neurosurgical technique. The contributions of neurosurgeons of former generations are found in the standardization of current neurosurgical operations and in the details of procedure that are set forth.

I am grateful to Eric Oldberg for encouraging me to become a neurosurgeon. I am deeply indebted to my late friend and teacher, Gilbert Horrax, for his moral support and calm understanding during my early experiences in neurosurgery, and also to Frank H. Lahey, who maintained a keen interest in neurosurgical procedures during his lifetime. I have incorporated many of his general surgical techniques. From Dandy, Peet, and Adson, each of whom I had the good fortune to know well, I have learned many safe "short cuts" which have been utilized in my daily practice. At every opportunity I have attempted to observe the operative procedures performed by other neurosurgeons, concentrating upon any minute detail which might be best suited to my ability and temperament.

A competent neurosurgeon must have a thorough knowledge of anatomy and gross pathology. He must also recognize his increasing dependence on the anesthesiologist who has specialized knowledge for handling neurosurgical cases. Since clinical and pathologic conditions vary, some flexibility in the selection and execution of a surgical procedure will always be necessary. A basic technique must be mastered.

however so that the operation may be performed in a chronologic order which permits maximum utilization of the assistants and instrument nurse. The development of a tidy technique demands a precise and orderly concept of the sequence of the operation and a disposition to follow the same technique unless the need for deviation becomes obvious. Unfortunately frequent innovations in technique are most appealing to the least experienced surgeon.

The satisfaction derived from bringing a neurosurgical procedure to its conclusion will be proportional to the surgeon's competence, skill and mastery of an accepted technique. If this Atlas contributes to this attainment these efforts will not be in vain.

I want to express my appreciation to Miss Eleanor Samsel, our head neurosurgical nurse, whose cooperation and essential help made this book possible. I also want to thank Dr. Lawrence S. Van Blaricom for his assistance. Acknowledgment for the drawings accompanies the plates. I wish to acknowledge further the work of the following artists—P. D. Malone, Robert Ullrich, Melford D. Diedrick, and Francis E. Steckel—and also the help of our Editorial Department. My thanks go to the staff of the W. B. Saunders Company for their help and encouragement.

REMOVAL OF SEBACEOUS CYST (WEN) OF THE SCALP

A A small area of the scalp is shaved.

In this particular instance the entire scalp has been shaved. Unless there are many wens of the scalp however it is necessary to shave only a small area immediately in the vicinity of the wen

B The scalp is incised to the capsule.

C Dissection of the capsule with scissors is begun.

D Completion of dissection of the capsule.

E Pressure is exerted with the thumb of each hand immediately next to the wen to deliver it intact

F The scalp is closed with interrupted black silk sutures.

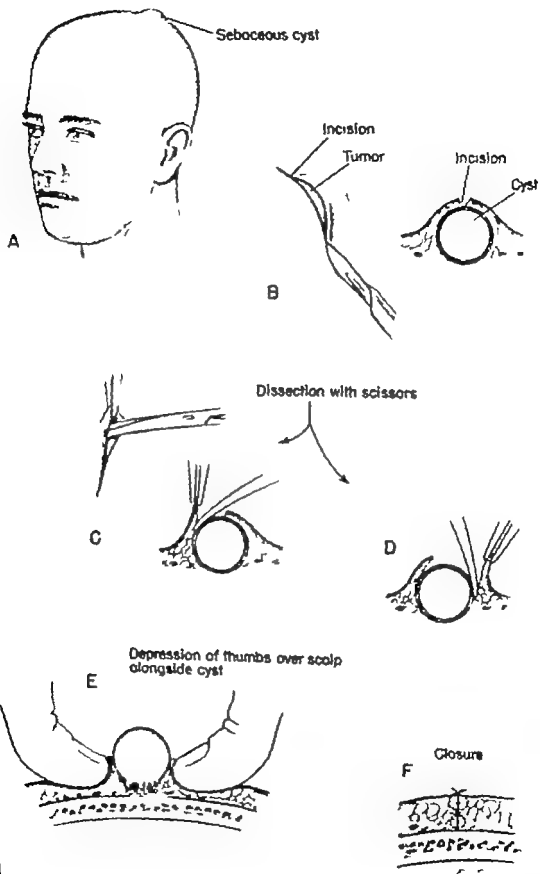

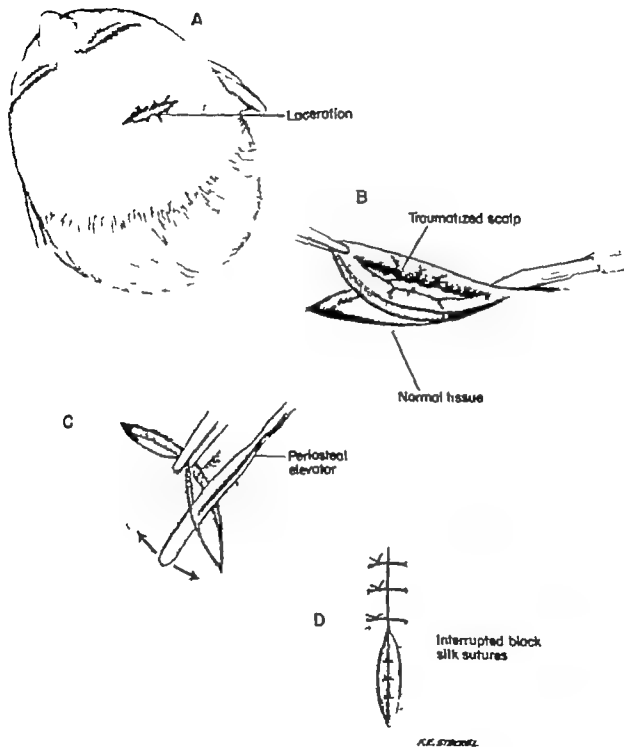

Plate 1

SCALP LACERATIONS PLASTIC PROCEDURES

- A Ragged laceration of scalp
- B Wide excision of traumatized scalp edges.
- C Undermining of scalp with periosteal elevator to allow mobilization of scalp for closure.
Bone is inspected visually and by palpation for possible fracture.
- D Closure.

SCALP LACERATIONS PLASTIC PROCEDURES

CIRSOID ANEURYSM OF SCALP

- A Location of cirsoid aneurysm. The type of scalp incision shown is made at a sufficient distance from the network of blood vessels.
- B Scalp flap turned down with periosteum and galea attached. Larger vessels at the base of the scalp flap are individually ligated well away from the malformation.

(Continued on Plate 4)

CIRSOID ANEURYSM OF SCALP

- C The galea is incised over the individual thin-walled, greatly enlarged veins.
- D The veins are opened.
- E Hemostat is inserted into the lumen of the veins and opened
- F The vein walls are completely removed

If vein walls in the smaller vessels are not removed recanalization takes place at a later date. Firm pressure bandages should not be applied because of the avascularity of the remaining scalp flap.

CIRSOID ANEURYSM OF SCALP

TRIGEMINAL NEURALGIA ALCOHOL INJECTION OF THE FIRST DIVISION AT THE SUPRAORBITAL AND INFRAORBITAL NERVES

1 Alcohol injection of the supraorbital nerve

- A The thumb is used to palpate the supraorbital notch. A fine 26 caliber needle is inserted into the notch usually the nerve can be palpated with the tip of the needle. As soon as the patient complains of radiating pain in the supraorbital division, a few drops of 80 per cent alcohol and 1 per cent procaine are injected.
- B Supraorbital and supratrochlear nerves.
- C Type of needle with short bevel used

2 Alcohol injection of the infraorbital nerve

- A The index finger of the left hand is placed over the inferior rim of the orbit the needle is inserted into the nasolabial fold
- B By gentle probing with the point of the needle the infraorbital canal is entered and 0.5 to 1.0 cc of alcohol injected

There should be immediate complete anesthesia of the infraorbital distribution. The ala of the nose and the medial portion of the upper lip should be tested for anesthesia. If they are completely anesthetized the injection will be successful.

In infraorbital alcohol injections, the bone over the maxillary sinus is occasionally found to be membranous in type and easily entered. Before alcohol is injected therefore, suction is exerted on the plunger to determine whether air enters the syringe. If so the needle should be replaced in the proper position. The needle should not be inserted too deeply into the infraorbital canal, since the point may enter the inferior portion of the orbit because of a thin membranous plate.

TRIGEMINAL NEURALGIA ALCOHOL INJECTION OF THE FIRST
DIVISION AT THE SUPRAORBITAL AND INFRAORBITAL NERVES

TRIGEMINAL NEURALGIA ALCOHOL INJECTION OF THE FIRST DIVISION AT THE SUPRAORBITAL AND INFRAORBITAL NERVES

1 Alcohol injection of the supraorbital nerve.

- A The thumb is used to palpate the supraorbital notch. A fine 26 caliber needle is inserted into the notch usually the nerve can be palpated with the tip of the needle. As soon as the patient complains of radiating pain in the supraorbital division, a few drops of 80 per cent alcohol and 1 per cent procaine are injected.
- B *Supraorbital and supratrochlear nerves*
- C Type of needle with short bevel used.

2 Alcohol injection of the infraorbital nerve.

- A The index finger of the left hand is placed over the inferior rim of the orbit the needle is inserted into the nasolabial fold
- B By gentle probing with the point of the needle, the infraorbital canal is entered and 0.5 to 1.0 cc. of alcohol injected.

There should be immediate complete anesthesia of the infraorbital distribution. The ala of the nose and the medial portion of the upper lip should be tested for anesthesia. If they are completely anesthetized the injection will be successful.

In infraorbital alcohol injections, the bone over the maxillary sinus is occasionally found to be membranous in type and easily entered. Before alcohol is injected, therefore, suction is exerted on the plunger to determine whether air enters the syringe. If so the needle should be replaced in the proper position. The needle should not be inserted too deeply into the infraorbital canal, since the point may enter the inferior portion of the orbit because of a thin membranous plate.

TRIGEMINAL NEURALGIA ALCOHOL INJECTION OF THE FIRST DIVISION AT THE SUPRAORBITAL AND INFRAORBITAL NERVES

TRIGEMINAL NEURALGIA ALCOHOL INJECTION OF THE SECOND DIVISION OF THE FIFTH CRANIAL NERVE AT THE FORAMEN ROTUNDUM

Alcohol injection of the second division of the trigeminal nerve is used only if the pain involves the roof of the mouth. Otherwise, infraorbital nerve injection is adequate, and is a simple procedure compared to the injection at the foramen rotundum.

A The position of the patient's head and the position of the surgeon are identical with those used in the third division alcohol injection. The needle is marked at 6.0 cm. with a tiny piece of adhesive, and is directed slightly more anteriorly than in the third division in order to strike the external pterygoid plate.

B *a-1* Needle in contact with the external pterygoid plate.

a-2 Needle directed slightly more anteriorly and toward the base of the skull, entering the pterygomaxillary fissure.

The nerve is usually reached at a depth of 5.5 cm., causing characteristic radiation of pain into the ala of the nose, upper lip and roof of the mouth. Two or three drops of 80 per cent alcohol and 1 per cent procaine are injected causing severe exacerbation of discomfort in these regions. Complete, immediate anesthesia follows. An additional 0.5 cc. of solution is then injected.

b The anterior approach to the second division is sometimes preferable, especially if there is an overhanging maxilla or if the pterygomaxillary fissure cannot be entered through the zygomatic notch. The needle passes medially at a 40 degree angle, anterior to the coronoid process and immediately posterior to the maxillary process.

As the needle enters the pterygomaxillary fissure (a narrow opening about 0.5 cm. wide, as demonstrated) it usually strikes either the external pterygoid plate behind or the posterior border of the maxilla in front. As a rule, the nerve is reached at a depth of 5.5 cm. depending on the width of the skull. It is important not to go deeper than 6.0 cm. at any time, because of possible injury to important structures, especially the optic nerve.

If the external pterygoid plate is struck initially it can be used as a valuable landmark. The foramen rotundum lies anteriorly and approximately 0.5 cm. deeper. If the posterior portion of the maxilla is reached before the pterygomaxillary fissure is entered, it will also serve as a guide: the fissure in which the nerve lies is bounded by the maxilla anteriorly and the external pterygoid plate posteriorly.

The nerve will be reached by gentle manipulation of the needle, unless unusually bony prominences make it impossible. As soon as the needle enters the nerve tissue, a spray of pain will be felt along the course of the nerve. Here again only a few drops of alcohol are injected at a time. If complete immediate anesthesia of the upper lip, ala of the nose and roof of the mouth takes place with two or three drops of alcohol, another 0.5 cc. is injected slowly.

TRIGEMINAL NEURALGIA ALCOHOL INJECTION OF THE SECOND
DIVISION OF THE FIFTH CRANIAL NERVE AT THE FORAMEN
ROTUNDUM

TRIGEMINAL NEURALGIA ALCOHOL INJECTION OF THE THIRD DIVISION AT THE FORAMEN OVALE

- A** Position of patient's head and surgeon: the patient's head is turned toward the left and the operator stands at the head of the table. A small area of skin immediately beneath the zygoma is sterilized. The inferior portion of the zygomatic notch is palpated firmly so that a small impression of the finger remains on the skin. The needle is first marked at 5.5 cm. with a tiny piece of wax or adhesive, then inserted.

The needle is directed slightly upward and backward to a depth of 4.5 cm. (the usual depth, which varies with the width of the skull). Immediate reaction is noted with the patient under light anesthesia, depending on the depth of anesthesia. The corner of the mouth is usually drawn up as the nerve is reached. If the nerve is not reached at the usual depth the needle is slightly withdrawn.

- B** 1 The needle is redirected slightly forward to contact the external pterygoid plate. This is an essential landmark because the foramen ovale lies just posterior and slightly medial to it.

2 When the pterygoid plate is located the needle is again slightly withdrawn and directed backward at a minimal degree until the nerve is entered, as evidenced by pain radiation.

It may be necessary to repeat this process several times, and the variation in depth of the foramen must also be considered. In some patients the foramen may be reached at a depth just under 4.5 cm.—and, rarely, even at a depth as great as 5.0 cm.—from the skin. When the nerve trunk has been entered and a few drops of alcohol injected, the plunger of the syringe is withdrawn to insure that the point of the needle is not in an artery. The patient's lower lip near the median line is tested for anesthesia. If the nerve has been struck properly the sensory loss is immediate in this portion of the lip, the lower gum, and half of the anterior two-thirds of the tongue.

When the level of anesthesia has been determined, another 0.5 to 1.0 cc. of alcohol is slowly injected. The needle is then withdrawn and pressure is applied with sterile gauze over the point of entrance, to prevent oozing from the skin. The patient is now asked to open his mouth. If the injection of the third division has been complete, the lower jaw will deviate distinctly toward the affected side, denoting that the motor root has been affected as well.

At times when the needle is in the proper position and depth there is no extension of pain down the jaw but a severe pain is present at the tip of the needle. Frequently there is radiation to the external portion of the ear anteriorly but the operator should be certain that the patient does not complain of pain deep in his ear canal.

TRIGEMINAL NEURALGIA ALCOHOL INJECTION OF THE THIRD
DIVISION AT THE FORAMEN OVALE

TRIGEMINAL NEURALGIA SUPRAORBITAL NEURECTOMY

- A Position.
- B Semicurved incision through shaved eyebrow
- C Relation of the supraorbital branches and the infratrochlear branch to the line of incision.
- D The main trunk of the supraorbital nerve extends through the bony foramen.
- E The thin, bony ledge of the orbital rim is removed with small rongeurs.
- F Avulsion of distal branches.

(Continued on Plate 9)

TRIGEMINAL NEURALGIA SUPRAORBITAL NEURECTOMY

- G Orbital fat is separated from the orbital roof by thin cotton pledgets.
- H The nerve is dissected and avulsed intraorbitally
- I Closure.
- J Bandage.
- K Rubber bag partially inflated with air placed over orbit.
- L Light pressure bandage applied over rubber bag to prevent swelling and extravasation of blood.

TRIGEMINAL NEURALGIA SUPRAORBITAL NEURECTOMY

- A Infraorbital nerve distribution
- B Position with head well extended.
- C Incision is made just above the gingival mucous membrane
- D The mucous membrane and periosteum are elevated from the maxillary bone to the infra orbital foramen
- E The nerve is separated and traction maintained with nerve hook.

(Continued on Plate 11)

- F Nerve branches can be separated from the soft tissues for a considerable distance with a periosteal elevator the nerve is avulsed from the infraorbital foramen.
- G A small metal probe is inserted into the infraorbital foramen and coagulation applied. The distal portion of the smaller branches is avulsed.
- H Closure is made with fine catgut which can be left *in situ*.
- I A loosely inflated bag is inserted over the maxilla.
- J A light pressure bandage is applied for a period of twelve to twenty-four hours.

TRIGEMINAL NEURALGIA INFRAORBITAL NEURECTOMY

TRIGEMINAL NEURALGIA INFERIOR DENTAL NEURECTOMY

- A A semicurved incision is made at the inferior margin of the angle of the jaw
- B The skin is reflected upward and the masseter muscle exposed
- C The masseter muscle has been split and separated with small vein retractors and a burr opening made through the central portion of the mandible, exposing the inferior dental nerve.
- D The nerve is divided and avulsed as far as possible.
The ends of the nerves usually break off at the edge of the bone that is exposed.
- E A nerve hook is inserted into the foramen cephalad and distally coagulation is applied.
The skin is closed with two layers of interrupted black silk sutures.

TRIGEMINAL NEURALGIA INFERIOR DENTAL NEURECTOMY

P. H. Mahoney

Severe postherpetic neuralgia of the first division of the fifth cranial nerve is not amenable to surgery if the skin is completely anesthetic in the area involved. If the skin is intensely hyperanesthetic, however with associated severe burning sensation and lightning pain, an elliptical excision of a portion of the involved skin can be made.

- A Excision.
- B Supraorbital nerve avulsed as in the operative technique for Supraorbital Neurectomy (Plates 8 and 9)
- C Scalp undercut in the extensive area involved by scar tissue.
- D Closure with two layers of interrupted black silk.

Drawing reproduced from Van Blaricom, L.S., and Horrax, G Chronic postherpetic neuralgia, J.A.M.A., 161 511-516, June 9 1956, by permission of the American Medical Association.

TRIGEMINAL NEURALGIA (POSTHERPETIC) NEURECTOMY

TRIGEMINAL NEURALGIA SENSORY ROOT OPERATIONS (INTRACRANIAL)

Using a temporal approach the sensory root of the fifth cranial nerve is subjected to compression, differential section or complete section

The scalp is prepared immediately preceding the introduction of anesthesia. The patient is questioned about the site of the pain regardless of the number of times the site is reported on the record

Intratracheal anesthesia is instituted. The lower extremities are wrapped with Ace bandages and the patient is placed in a sitting position

- A Outline of the site of incision.
- B Index finger is placed immediately beneath the zygomatic process incision is outlined. The incision is brought down to the tip of the index finger so that it extends over the zygomatic process but not beneath it.
- C Scalp and temporal muscle fibers are separated with a self retaining retractor exposing the junction of the squamous portion of the temporal bone and the zygomatic process. One burr opening is made immediately above the zygomatic process and another 1 or 2 cm. above this process

In the majority of patients there is a bony ledge or enostosis, as indicated in the inset. This allows removal without damage to the dura

- D A rectangular portion of bone is removed

In most instances the lower portion of the opening should be wider anteriorly than is the superior portion. This prevents unsightly depression in the temporal region at a later date and, furthermore, tends to make the approach easier

The dura is separated from the lower edge of the squamous portion of the temporal bone with a right angle periosteal elevator

Inset A cotton pledget is then inserted between the separated dura and the bony edge the inferior ledge is removed with a Kerrison punch.

(Continued on Plates 15 and 16)

TRIGEMINAL NEURALGIA SENSORY ROOT OPERATIONS (INTRACRANIAL)

TRIGEMINAL NEURALGIA SENSORY ROOT OPERATIONS (INTRACRANIAL)

- E** The dura is gently elevated with a malleable blade retractor. The dura is separated from the floor of the temporal fossa anteriorly toward the foramen rotundum, with a rolled cotton pledget or if firmly adherent, with a periosteal elevator.

Annoying venous oozing from the dural attachments between the second and third divisions may occur. If this happens, a large, soft piece of bone wax is inserted into the cavity and gently compressed medially against the oozing portion. If a large enough piece has been inserted all oozing will stop. The wax can be readily molded and the operation completed without unnecessary bleeding. It is important that the sensory root is not divided until the visualization is adequate and clear. All bone wax should be removed before closure is made.

At times bony projections or spicules arise from the floor of the skull; these can be readily removed with a fine chisel and mallet.

After the maxillary division has been identified at the foramen rotundum, the dura is separated posteriorly toward the foramen ovale. The middle meningeal artery will become visible. The foramen spinosum is plugged with a wisp of cotton and covered with a small piece of wax; the artery is divided, as in the *buse*. The distal end of the cut artery is occluded with the electro-surgical unit.

- F** After the middle meningeal artery has been divided, the line of cleavage between the temporal dura and the dura propria is developed by blunt dissection with a firmly rolled cotton pledget. With firm pressure kept constantly over the anterior rim of the foramen ovale, this dissection is made by a rubbing movement continued medially and posteriorly for a distance of 3 or 4 mm., uncovering the anterior portion of the third division. This causes an angle to develop in the dura immediately lateral to the third division. By a shallow incision with a scalpel exactly at that level the temporal dura is split over the petrosal fibers. The outer layer of the dura remains intact over the petrosal nerves, thus preventing injury to them.

The temporal dura is then separated from the dura propria lying over the ganglion of the posterior root by similar sweeping motions—that is, by down and up movements. The temporal dura is reflected from the dura propria over the sensory root approximately to the apex of the temporal bone. This level can be readily detected by the fine transverse fibers which will appear in the dura propria over the sensory root.

- G** Approximate relationship of foramen spinosum to third division and petrosal nerves.

- H** A lighted retractor is used. A semicurved incision is made through the dura propria and arachnoid and elevated with the end of the retractor exposing the sensory root.

If the patient and surgeon have decided that a compression procedure should be performed, the sensory root is lightly massaged with a cotton pledget or staphylotherapy at this time. If the differential section is to be instituted, the central portion of the sensory root fibers can be readily separated to identify the motor root.

- I** The inferior portion of sensory root is elevated and retracted laterally exposing motor root.

If the second and third divisions of the fifth cranial nerve are involved, a sharp-pointed knife is used to divide the sensory root as it is elevated with the nerve hook.

Great care must be taken in dividing all the fibers in the lateral gutter since a few of the fibers may escape section if the necessary care is not taken at that point.

A few sensory fibers may be closely associated with the motor root and be left intact if thorough inspection is not made. In most instances the motor root is divided into two or three small branches which can be readily separated from each other. Care should be taken, however, that they are not mistaken for sensory fibers.

- J** Motor root and ophthalmic sensory fibers are intact and the sensory fibers corresponding to the second and third divisions are divided.

(Continued on Plate 16)

TRIGEMINAL NEURALGIA SENSORY ROOT OPERATIONS (INTRACRANIAL)

TRIGEMINAL NEURALGIA SENSORY ROOT OPERATIONS (INTRACRANIAL)

A small piece of Gelfoam, covering the sensory root, is inserted immediately over the incision made in the dura propria and arachnoid. All bleeding points from the dura are stopped. Normal saline may be injected into the subdural space so that the cavity is completely obliterated.

K The temporal muscle is closed with several layers of interrupted black silk. The temporal fascia should also be closed carefully to prevent later unsightly depression of the tissues. A small dressing is applied.

L A Buller's shield is attached to the eye in all cases, regardless of whether compression or sensory root avulsion has been performed. The shield is removed as soon as the corneal reflex is intact.

TRIGEMINAL NEURALGIA · SENSORY ROOT OPERATIONS
(INTRACRANIAL)

OCCIPITAL NEURALGIA NEURECTOMY

Two methods of occipital neurectomy may be used to advantage.

- A Incision is made lateral to and just above occipital protuberance. Scalp is incised to fascia containing bundle of occipital nerves and arteries.
- B The greater occipital nerve branches and vessels are exposed.
- C Blunt scissors are used to separate nerves from fascia and muscle.
- D Avulsion of distal ends of greater occipital nerves.
- E Avulsion of proximal ends of nerves.

Arteries are usually occluded with the electrosurgical unit and divided, with the hope that component vascular discomfort may be ameliorated.

(Continued on Plate 18)

OCCIPITAL NEURALGIA NEURECTOMY

The alternate method of occipital neurectomy through a midline incision is outlined here. With this procedure it is possible to remove the upper cervical branches as they emerge along the cervical canal. It is more difficult, however, to resect the auricular branch, as may be necessary at times. In that instance the procedure demonstrated in Plate 17 is preferable, since the auricular branches can be readily exposed and divided.

The lettered steps of this procedure are self-explanatory.

SUPERFICIAL TEMPORAL ARTERITIS ARTERIECTOMY

- A Incision is made over the course of the superficial temporal artery through the superficial tissues.
- B The soft tissues are separated superficially with the dissecting Metzenbaum scissors.
- C The bundle of arteries, veins and fine temporocutaneous branches of the fifth cranial nerve is separated from the temporal muscle fascia.
- D The bundle raised *en bloc* with a large nerve hook the segment is resected between ligatures.
- E The resected mass of arteries veins and nerves.

Closure of the skin is made with interrupted end-on mattress sutures.

BLEPHAROSPASM AND SPASMODIC FACIAL TIC DIFFERENTIAL SECTION OF FACIAL NERVE

A Line of incision.

B Small facial branches exposed distal to the parotid gland. By stimulation with faradic current the various muscle innervations can be readily determined, even though the patient is under anesthesia.

Thus, if the patient has severe facial spasm of the orbicularis oculi inferioris and superioris previous to surgery (blepharospasm) these fibers can be readily determined by stimulation as long as the entire half of the face is exposed during surgery.

Branches which, when stimulated, simulate the contractions complained of by the patient are divided. In most instances it is preferable to omit sectioning of the branches that innervate the frontalis muscles.

C Branches divided so that stimulation of the facial nerve causes only mild contraction of the previously involved muscles.

OSTEOMA OF FRONTAL SINUS

A Anteroposterior x ray film demonstrating osteoma and frontal sinus.

R Lateral x ray film showing the same.

(Continued on Plate 23)

OSTEOMA OF FRONTAL SINUS

OSTEOMA OF FRONTAL SINUS

Osteoma in the frontal sinus should be removed only if it has caused local disturbance, such as downward outward displacement of eyeball or intracranial extension

- {1} Modified coronal incision osteoplastic bone flap
- {2} Frontal sinus open demonstrating distortion of the orbital plate.
- {3} Roof of the sinus removed and osteoma enucleated.
- {4} Floor of the sinus removed exposing the orbital tissues.

The open portion of the sinus can be readily repaired with Gelfoam and a small stamp of muscle. The bone flap is replaced and the usual closure made.

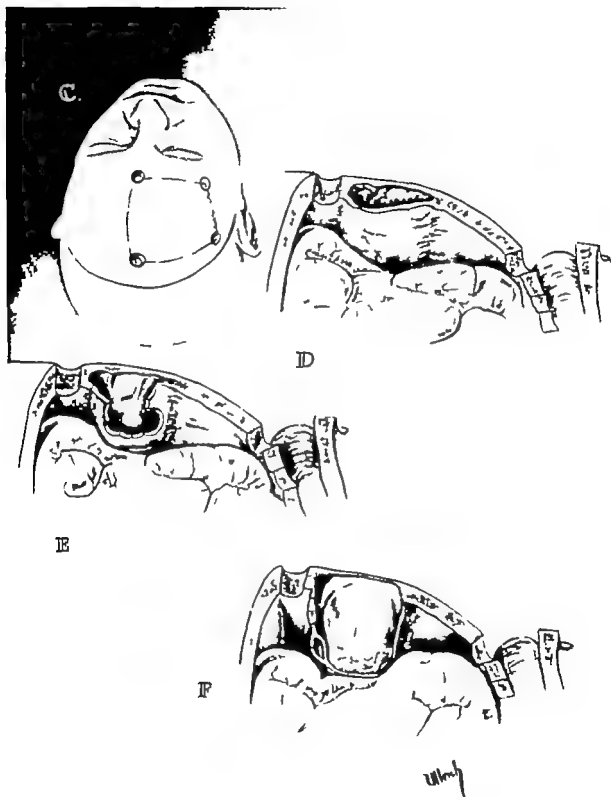

OSTEOMA OF FRONTAL SINUS

Osteoma in the frontal sinus should be removed only if it has caused local disturbance, such as downward, outward displacement of eyeball or intracranial extension.

- C Modified coronal incision osteoplastic bone flap
- D Frontal sinus open demonstrating distortion of the orbital plate.
- E Roof of the sinus removed and osteoma enucleated.
- F Floor of the sinus removed exposing the orbital tissues.

The open portion of the sinus can be readily repaired with Gelfoam and a small stamp of muscle. The bone flap is replaced and the usual closure made.

OSTEOMA OF FRONTAL SINUS

INTRAORBITAL TUMORS

Intraorbital tumors can be readily exposed transcranially. The surgical approach is similar to the anterior approach to pituitary adenomas, with the exception that the dura is separated from the orbital plate as in orbital decompression for malignant exophthalmos. (Refer to Chromophobe and Chromophil Pituitary Adenomas, Plate 45 and Malignant Exophthalmos Bilateral Orbital Decompression, Plates 129-131)

The orbital roof is removed to allow exploration. In most instances this provides adequate exposure for removal of the tumor. For tumors involving the lacrimal gland or located in the lateral-inferior portion of the orbit, the lateral wall of the orbit must also be removed.

Before craniotomy is performed, a temporary tarsorrhaphy is made. This is particularly important in patients with pronounced displacement of the eyeball.

Intraorbital glioma of the optic nerve the orbital roof has been removed and the ocular muscles separated, exposing the tumor.

The roof of the optic canal is removed if the tumor extends into it. At times the tumor is dumbbell in shape, the posterior portion extending to the optic chiasm. In these cases the tumor is excised to the optic chiasm.

If the patient still has useful vision, however, simple decompression followed by x-ray treatment should be instituted as an initial step.

EXOSTOSIS OF SKULL

A Transverse incision made in the crease of the scalp

Under ordinary circumstances exostosis of the skull need not be removed, unless it is disfiguring, as when found in the frontal region.

B Cross section of the osteoma.

C Burr openings made to the inner plate.

D Bone between burr openings removed with a rongeur leaving the inner plate intact.

SYNOSTOSIS CRANII OXYCEPHALY AND SCAPHOCEPHALY

- A Oxycephaly
- B Coronal incision with transverse extension into the temporal region.
- C Site of burr openings. Strips of bone 2 cm. in width connecting burr openings are removed with rongeurs. The squamous bone is removed inferiorly.
- D
- E The dura is opened through a gutter made in the bone, except in the sagittal plane.

This procedure is carried out in an attempt to regain a reasonably normal contour of the skull as growth continues, with the prime objective of relieving intracranial pressure.

(Continued on Plate 27)

SKULL DEFECTS PLASTIC PROCEDURES

- A Bone defect in the skull
- B Gutta-percha placed over the bone defect to determine the proper size and pattern.
- C Exact pattern placed over the tantalum plate so that a plate of the proper size can be cut
- D Tantalum plate molded on a molding block.
- E Drill opening made in bone edge. The size of the drill and depth are determined by the size of the tantalum screw
- F Drill opening in the tantalum plate is countersunk.
- G Screw head is then flush with the edge of the plate.
- H Plate *in situ*

(Continued on Plate 29)

SKULL DEFECTS PLASTIC PROCEDURES

Plastic with acrylic material is often preferable

I Countersinking on a ledge the outer plate is removed with a special drill.

J Acrylic plate in position

The advantage of the acrylic plate is elimination of dead space between the dura and the plate. The dotted lines indicate small drill openings made through the plate so that tissue can grow through these openings.

HEAD INJURIES DEPRESSED COMMUNUTED SKULL FRACTURE

- A Scalp incision should be made well away from the edges of the depressed skull fracture.
- B Burr openings are made through healthy bone around the edges of the fracture.
- C The lacerated dura is repaired the brain is inspected beneath the comminuted fracture.
- D Bone flap is replaced after fragments have been everted. The scalp is sutured with a single layer of interrupted stainless steel wire.

HEAD INJURIES SUBDURAL HEMATOMA

- A Position of patient.
- B Relative locations of scalp incisions over the parietal area approximately 4.5 cm. from the midline. The anterior incisions are outlined and the usual drapes applied. Burr openings are then made over the parietal region.

As the dura is exposed by burr openings made on each side, the presence or absence of a subdural hematoma can be determined by its color. The dura overlying the hematoma usually has a bluish tinge. In rare instances an aberrant or accessory venous sinus may lie immediately beneath the burr opening, simulating the appearance of a subdural hematoma.

- C Hematoma visible through the dura.
Inset (between C and D) Appearance of normal dura and of dura overlying hematoma on opposite side.
- D Dura opened. The outer membrane of the hematoma is as thick as the dura at times, but definitely more friable. Chocolate-colored, liquefied contents will pour out. A catheter is inserted and the cavity washed out with normal saline solution.

If partially organized material is present, hydrogen peroxide may be inserted with a syringe. This usually tends to detach the organized fragments. Care must be taken to avoid aspirating the foam that results from the insertion of hydrogen peroxide, since the suction tube will become clogged. It is better to wait for a minute or two and then wash it out thoroughly with saline solution.

- E Cross section with catheter in the hematoma cavity. The relative thickness of the outer and inner membranes is shown, with displacement of the cerebral hemisphere.
- F Catheter remains in cavity for twenty-four to forty-eight hours.

The two anterior incisions shown in B are opened only if hematomas are not found in the parietal area.

If the hematoma has been present for several months, the brain does not expand immediately. Expansion takes place gradually in three or four days, and the degree of expansion can be verified by postoperative roentgenograms. The cavity resulting from the evacuation of a hematoma is always filled with air; consequently an excellent indication of the degree of expansion that occurs can be visualized by anteroposterior x-ray films made on successive days.

If the hematoma is completely organized, it can be removed either through a subtemporal decompression site or through an enlargement of the burr openings.

HEAD INJURIES SUBDURAL HEMATOMA

HEAD INJURIES EXTRADURAL HEMATOMA

- A Extradural hematoma with displacement of cerebral tissue.
- B Line of incision is that used in Sensory Root Operations (Plate 14) a similar exposure is made.
- C Fracture line burr openings made outline of the squamous portion of the temporal bone to be removed.

(Continued on Plate 33)

HEAD INJURIES EXTRADURAL HEMATOMA

D Clot removed with suction

E Temporal dura elevated foramen spinosum occluded with a small wisp of cotton inserted with a nerve hook and foramen covered with wax.

Meningeal vessels may also be occluded with the electrosurgical unit. All bleeding points are carefully controlled.

F Closure. Catheter which drains into a thin rubber bag, is removed in twenty-four hours

HEAD INJURIES EXTRADURAL HEMATOMA

HEAD INJURIES OSSIFIED SUBDURAL HEMATOMA

- A** Completely ossified subdural hematoma lying along the falx and extending over the medial surface of the cerebral hemisphere.

Inset Ossified hematoma removed.

- B** Cavity remaining after the hematoma has been removed, demonstrating greatly increased vascularity of the cortical tissues

CERVICAL TRACTION WITH VINKE TONGS

The patient is placed on the operating table in a supine position

- A A small area of scalp is prepared in each temporoparietal region.
- B After the site for insertion of the burr openings has been determined, impressions are made on the scalp with tongs.
- C The scalp area is anesthetized with local infiltration of procaine.
- D A stab incision is made.
- E The periosteum is freed

(Continued on Plate 36)

LARGE HYPEROSTOSING MENINGIOMA

This procedure is suitable for the large hyperostosing meningioma, involving mostly bone, periosteum and dura, with slight intradural extension. It is also applicable to the large solitary tumor involving bone, periosteum and dura, and depressing but not invading brain tissue.

A Location of tumor and line of incision.

B Galea separated from periosteum.

C Scalp flap reflected periosteum incised.

(Continued on Plates 38 and 39)

LARGE HYPEROSTOSING MENINGIOMA

LARGE HYPEROSTOSING MENINGIOMA

D Multiple burr openings made encircling the tumor mass.

The extent of bone involved with the tumor can be determined in this manner and the intervening bone between the burr openings can be easily removed with a wide rongeur. Because of brisk bleeding from the burr openings as the bone is removed with rongeurs, it may be necessary at times to insert large temporary plugs of wax while proceeding with the removal of bone.

E Dura incised, encircling the entire tumor mass

(Continued on Plate 39)

LARGE HYPEROSTOSING MENINGIOMA

LARGE HYPEROSTOSING MENINGIOMA

- F Completion of operative procedure. The dural defect is again closed with the periosteal graft or dural artificial substitute. The bony defect is repaired with either tantalum plate or plastic material and the scalp flap resutured.
- G

LARGE HYPEROSTOSING MENINGIOMA

MENINGIOMA OF THE CONVEXITY

Convexity meningiomas with a broad dural attachment may be surgically extirpated without decreasing bulk by the use of the electrosurgical unit.

A Meningioma with a broad dural attachment enostosis

B Type of scalp incision and bone flap The enostosis is completely drilled out to the outer plate.

If the outer plate is also involved with tumor the entire area is removed and replaced by a bone, stainless steel or acrylic plate.

The dura is incised at right angles to the tumor well away from its edge in this way the exact extent of dural involvement can be determined. The dura is then incised, encircling the tumor care is taken that no tumor is allowed to remain attached to the dural edges.

Meningiomas that have a broad base can be removed intact without exerting excessive traction on the cortical tissues.

C Arachnoidal attachment to the tumor mass has been coagulated immediately over the tumor edge and then brushed aside, most of the traction being exerted on the tumor itself rather than on the cortical tissues.

All entering vessels are individually sealed off with the electrosurgical unit. For this reason it may be necessary to encircle the tumor completely two or three times at various depths.

(Continued on Plate 41)

MENINGIOMA OF THE CONVEXITY

Meningioma with broad base
invading dura and bone

MENINGIOMA OF THE CONVEXITY

- D** The tumor is then lifted from its bed and the vessels attached to the inferior surface are occluded and divided.
- E** The tumor is removed. A large cotton ball is immediately inserted into the tumor cavity the ball should fill the entire cavity. A glass suction tube is applied to the cotton ball.

As the cotton ball is gently removed, the smaller cortical vessels in the brain tissue are coagulated against the cotton as they come into view while the cotton ball is being elevated.

The dura is repaired either with a periosteal graft obtained from the scalp flap or with a dural substitute.

If the cavity is large, catheter drainage is instituted for a period of two or three days.

MENINGIOMA OF THE CONVEXITY

SUBMERGED OR "ICEBERG" TYPE OF MENINGIOMA

Such a meningioma involves only a small portion of the dura.

- A Cross section of the submerged type of meningioma with a narrow attachment to the dura. The cortex covers the bulk of the tumor with the exception of the small narrow neck.
- B An osteoplastic bone flap is turned down the dura is incised well away from the tumor at right angles until tumor tissue is encountered. The dura is then opened, encircling the attached tumor
- C The tumor should be scooped out with the electrosurgical unit, allowing only a shell of tumor to remain

If the tumor were removed in one mass, the cortex overlying the submerged tumor would be damaged considerably

- D The tumor wall can then be removed and brought out through a relatively small cortical opening.

In this manner trauma to the surface brain tissue is kept at a minimum.

- E The capsule of the evacuated tumor is delivered from its bed.

The dural opening is closed with a dural substitute or with a portion of galea excised from the scalp flap, as demonstrated in *Technique for Obtaining Dural Graft from Scalp Flap* (Plate 113)

SUBMERGED OR "ICEBERG" TYPE OF MENINGIOMA

OLFACTORY GROOVE OR CRIBRIFORM PLATE MENINGIOMA

- A Outline of bone flap and location of tumor from anterior view
- B Position of the patient head slightly extended, body in a moderate Fowler's position.
- C Tumor in relation to the floor of the skull and the anterior fossa.
- D Oblique view of the tumor demonstrating the groove made in the tumor by the falx, posterior displacement of the callosal arteries and downward compression of the optic chiasm.
- E Greatly thinned shell of the frontal lobe removed, exposing the tumor

(Continued on Plates 44 and 45)

OLFACTORY GROOVE OR CRIBRIFORM PLATE MENINGIOMA

OLFACTORY GROOVE OR CRIBRIFORM PLATE MENINGIOMA

- F** Larger vessels over the capsule of the tumor have been coagulated and the tumor gutted with electrosurgical unit.

At the time of the looping, a glass suction tube is kept in the excised portion of the tumor. This greatly facilitates the looping with the electrosurgical knife, by preventing excess eschar formation on the loop and excessive transmission of heat, and by keeping the field free from blood at the point that the scalloping takes place.

- G** Bleeding points carefully controlled. The anterior medial wall of the tumor is retracted posteriorly away from the bony attachment to the cribriform plate. The bleeding points in the bone are controlled with wax.

- H** Falx incised and a wedge-shaped portion removed

- I** This allows the medial retraction of the shallow tumor wall, which has made a deep nest in the medial position of the opposite hemisphere.

(Continued on Plate 45)

OLFACTORY GROOVE OR CRIBRIFORM PLATE MENINGIOMA

OLFACTORY GROOVE OR CRIBRIFORM PLATE MENINGIOMA

- J Bony attachment over the cribriform plate.
- K Involved bony enostosis removed with a chisel to prevent recurrence.
- L Cavity after removal of tumor

If in the removal of the bony enostosis the mucous membranes of the ethmoid sinuses are exposed these should be reinforced to prevent rhinorrhea. (Refer to Cerebrospinal Rhinorrhea Surgical Treatment, Plates 139-141)

OLFACTORY GROOVE OR CRIBRIFORM PLATE MENINGIOMA

PARASAGITTAL MENINGIOMA
Associated with Enostosis and Involving
the Lateral Portion of the Sagittal Sinus

A. Type of scalp incision bone flap turned down well across the midline.

In this particular instance the enostosis readily separates from the tumor

Anterior and posterior burr openings are made on each side of the sagittal sinus and are connected with a Montanovesi rongeur rather than with the Gigli saw

(Continued on Plates 47 48 and 49)

PARASAGITTAL MENINGIOMA

Associated with Enostosis and Involving
the Lateral Portion of the Sagittal Sinus

A

Sagittal sinus

Ullrich

PARASAGITTAL MENINGIOMA

Associated with Enostosis and Involving
the Lateral Portion of the Sagittal Sinus

B The enostosis is deeply imbedded in the tumor proper and involves the lateral portion of the sagittal sinus.

In this particular instance, allowing the involved bone to remain *in situ* immediately over the tumor (as shown) is preferable. The bone may be either removed with a periosteal elevator after the bone flap has been turned down or allowed to remain while the tumor is being removed.

(Continued on Plates 48 and 49)

PARASAGITTAL MENINGIOMA

Associated with Enostosis and Involving
the Lateral Portion of the Sagittal Sinus

PARASAGITTAL MENINGIOMA

Associated with Enostosis and Involving
the Lateral Portion of the Sagittal Sinus

- C Tumor completely encircled with a dural incision which leaves only a small margin of normal dura attached to tumor
- D Cross section parasagittal meningioma involving the bone and lateral wall of the sagittal sinus.
- E Tumor removed from its bed, allowing the medial portion of the dural flap attached to the lateral margin of the sagittal sinus to remain intact.
- F Curved hemostats occlude the lateral margin of the sagittal sinus. As each hemostat is applied, the healthy dural edges of the sinus are divided with scissors.
- G After excision of the tumor interrupted black silk sutures are inserted as the ligature is tied, each hemostat is removed.
- H Completion of closure of the edges of the sinus leaving the major channel intact.

The dural defect is repaired with a perosteal or artificial graft. The tumor invading the inner plate of the bone flap is removed with the electric drill to the external plate if this plate is not involved with tumor. If tumor has invaded the external plate, the defect is closed with an artificial bone graft.

The scalp is closed with a single layer of end-on mattress stainless steel wire.

(Continued on Plate 49)

PARASAGITTAL MENINGIOMA

Associated with Enostosis and Involving
the Lateral Portion of the Sagittal Sinus

PARASAGITTAL MENINGIOMA

Associated with Enostosis and Involving
the Lateral Portion of the Sagittal Sinus

Meningioma extending to the edge of the lateral sinus but not involving the wall.

- I Bone flap turned down from well across the midline dura incised around the tumor to the wall of the sinus.
- J Tumor removed from its bed.
- K Curved hemostats placed along the lateral edge of the sagittal sinus.
- L Fine silk sutures placed along the edge of the sagittal sinus.
- M Tumor cavity and surrounding structures. Dural defect is repaired

PARASAGITTAL MENINGIOMA

Associated with Enostosis and Involving
the Lateral Portion of the Sagittal Sinus

HYPEROSTOSING SPHENOID WING MENINGIOMA

During the introduction of anesthesia considerable care should be exercised to protect the cornea of the exophthalmic eye. After the patient has been anesthetized, the eyelids are closed by temporary interrupted mattress sutures. (Refer to Malignant Exophthalmos Temporary Canthorraphy Plate 127)

- A Line of incision. The sagittal portion of the incision should lie in the exact midline and be brought down in the form of a question mark to the zygomatic process
- B Bone flap outline.
- C Greatly thickened squamous portion of the temporal bone is removed by making multiple burr openings, as demonstrated, so that the severely eburnated bone can be readily removed. Burr openings are also made over the thickened portion of the orbital plate to facilitate removal of the plate with rongeurs.

(Continued on Plates 51 and 52)

HYPEROSTOSING SPHENOID WING MENINGIOMA

HYPEROSTOSING SPHENOID WING MENINGIOMA

D Compression of the orbital contents causing the exophthalmos method of removal of the greatly thickened, eburnated bone.

E Solid intracranial tumor

In most instances the tumor associated with the hyperostosing sphenoid wing meningioma is *en plaque* rather than a globular type. At times, however a solid tumor does extend intracranially and should be excised.

F Dural graft sutured into the defect.

G Cotton pledgets removed and dura completely closed.

H Recession of the eyeball and decompression of the orbital tissues after removal of the orbital plate.

(Continued on Plate 52)

HYPEROSTOSING SPHENOID WING MENINGIOMA

D

E

F

G

H

HYPEROSTOSING SPHENOID WING MENINGIOMA

If the anterior clinoid is also involved, it should be removed

I Greatly thickened anterior clinoid honeycombed with a special drill.

Insert Removal of the interlacing bone left by the burr openings with chisel and mallet.

J Orbital fascia opened to determine whether meningioma *en plaque* is present intraorbitally

K If tumor is present, the orbital fascia involved by the tumor should be completely excised

L Frontotemporal dura along the sphenoid wing involved with a layer of tumor—the so-called *meningioma en plaque*

The dura should be separated from the anterior portion of the temporal fossa, and the dura involved with the tumor should be completely excised. If only a small area of dura is invaded by tumor it may be destroyed with electrocoagulation however complete excision of this area is preferable.

The temporal muscle is also occasionally invaded by tumor. If this occurs, the muscle can be readily excised.

The usual closure is made and a catheter allowed to remain in the cavity for twenty-four to thirty-six hours. The temporary lid suture is removed as soon as the postoperative edema has subsided.

HYPEROSTOSING SPHENOID WING MENINGIOMA

MENINGIOMA OF THE POSTERIOR CLINOID AND SELLA TURCICA TEMPORAL APPROACH

- A Temporal approach type of incision. The squamous portion of the temporal bone is removed through the vertical incision. Sufficient room is usually obtained without opening the posterior line of incision. The bone flap (outlined) is turned down only if exposure through the original opening is inadequate.
- B Anterior incision only opened as in operation for Trigeminal Neuralgia (Plate 14)
- C Normal anatomic structures.
- D Meningioma of the clivus, displacing the pons posteriorly partially obstructing the aqueduct of Sylvius, and extending superiorly into the third ventricle. The optic chiasm is prefixed making it impossible to approach the tumor anteriorly
- E Temporal lobe elevated, exposing tumor. The third cranial nerve may be displaced laterally as well as posteriorly or it may be carried superiorly with the tumor and greatly stretched.
- F Relationship of distorted structures after removal of tumor

MENINGIOMA OF THE POSTERIOR CLINOID AND SELLA TURCICA, TEMPORAL APPROACH

CHORDOMA PARASELLAR, SELLAR AND POSTERIOR CLINOID TEMPORAL APPROACH

Chordomas are exposed in the same manner as craniopharyngiomas and pituitary adenomas with a prefixed chiasm (Refer to Large Craniopharyngioma with Prefixed Chiasm Temporal Approach, Plate 58)

- A Relationship of chordoma to sella pons and anterior third ventricle with a prefixed optic chiasm erosion of posterior clinoid and upper portion of clivus.
- B Relationship to blood vessels and chiasm lateral view
- C Relationship to blood vessels and chiasm, posterior view
- D Tumor completely extradural

Thus the tumor can be extirpated extradurally with the incision made through the capsule just above the cavernous sinus.

Tumors involving the posterior clinoid the upper portion of the clivus or the sella turcica that are limited anteriorly by the chiasm of the optic nerve, posteriorly by the pons and superiorly by the third ventricle should be attacked by the temporal route. This is especially true if the chiasm of the optic nerve is prefixed.

CHORDOMA PARASELLAR, SELLAR AND POSTERIOR CLINOID TEMPORAL APPROACH

CHROMOPHOBE AND CHROMOPHIL PITUITARY ADENOMAS FRONTAL APPROACH

An incision is made similar to that demonstrated in Hypophysectomy (Plate 56), up to the point of exposure of the adenoma.

Top inset Type of incision made in the dura single curvilinear opening with the anterior flap attached with interrupted silk sutures to the galea of the scalp flap.

The chiasm is fixed and the adenoma is shown protruding between the stretched optic nerves. The small vessels over the capsule of the adenoma are sealed off with the electro-surgical unit and a portion of the capsule is removed with a sharp-pointed knife.

A : Contents are then evacuated with a pituitary scoop.

B Further evacuation of contents by suction.

C Removal of the redundant capsule.

Care must be taken to control all bleeding points before closure is made

CHROMOPHOBE AND CHROMOPHIL PITUITARY ADENOMAS
FRONTAL APPROACH

HYPOPHYSECTOMY

As the patient is being draped for frontal craniotomy under intratracheal anesthesia, spinal fluid may be withdrawn from the lumbar canal or urea solution given intravenously. If urea solution is instituted, an indwelling catheter in the bladder is important.

- A With the patient in Fowler's position and the head slightly flexed a frontal scalp flap is reflected and a bone flap turned down in the location outlined
- B The dura is opened with the pedicle placed anteriorly with a slightly curved incision and sutured to the scalp flap for traction. The frontal lobe is then slowly elevated allowing as much cerebrospinal fluid as possible to escape. The right optic nerve is identified
- C The arachnoid of the prechiasmatic cistern is opened. The right and left optic nerves, as well as the anterior portion of the chiasm and the pituitary stalk, are visualized
- D The stalk is coagulated and divided
- E If the natural opening of the diaphragm of the sella turcica is not sufficiently large, an incision is made in a stellate fashion, care being taken not to enter the venous sinuses.
- F The diaphragm of the sella turcica is opened widely

(Continued on Plate 57)

HYPOPHYSECTOMY

G An open pituitary scoop is inserted to the posterior clinoid freeing the capsule if possible.

If the tuberculum of the sella projects posteriorly the capsule cannot be freed from its anterior wall initially without removing the bony projection. On the other hand if no projection is present, the dissection can be started anteriorly and the pituitary body removed intact.

H If it is necessary to remove the pituitary body piecemeal, the capsule must be removed

I After total enucleation small bleeding places occasionally occur. Gelfoam is inserted into the cavity and allowed to remain against the walls of the sella. Light pressure is applied for a few minutes.

J Excess Gelfoam is removed after the oozing has stopped.

A catheter is inserted into the sella and the usual dural closure made. The catheter is removed in twenty-four to forty-eight hours.

HYPOPHYSECTOMY

LARGE CRANIOPHARYNGIOMA WITH PREFIXED CHIASM TEMPORAL APPROACH

- A** Type of incision. The squamous portion of the temporal bone is removed through the vertical incision.

This approach is used with patients with severe internal hydrocephalus. Usually sufficient exposure can be obtained without turning the bone flap as outlined. The posterior line of incision does not have to be opened unless it is necessary to turn down the bone flap as well as remove the bone with rongeurs.

- B** Temporal lobe elevated and exposure made, showing the right optic nerve displaced anteriorly and the positions of the carotid artery and the third cranial nerve. The capsule of the tumor is opened.

If the contents are merely cystic, the capsule readily separates from the inferior portion of the third ventricle and the surrounding tissues and can be removed piecemeal or in one segment. On the other hand if the tumor consists of a considerable amount of solid tissue, it can be removed intracapsularly.

- C** Complete extirpation of capsule.

This step was possible in this particular operation

(Continued on Plate 59)

LARGE CRANIOPHARYNGIOMA WITH PREFIXED CHIASM FRONTAL APPROACH

Postmortem examination showing the difficulties encountered in the frontal approach to craniopharyngioma. Portions of the right frontal lobe were resected and the right optic nerve was divided. A very incomplete intracapsular enucleation was possible. The temporal approach is preferable in this type of condition.

LARGE CRANIOPHARYNGIOMA WITH PREFIXED CHIASM
FRONTAL APPROACH

GLIOMA FRONTAL LOBECTOMY

- A Exposure with the dura turned medially and the base of the pedicle at the level of the sagittal sinus.
- B The cortical veins are occluded and divided with the electrosurgical unit.
- C The frontal lobe is retracted from the midline the branches of the frontopolar artery are divided
- D The frontal lobe is elevated from the orbital plate cotton pledgets are inserted to the level of the sphenoid wing.

(Continued on Plate 61)

GLIOMA FRONTAL LOBECTOMY

GLIOMA FRONTAL LOBECTOMY

- E The vessels of the pia arachnoid are occluded with the electrosurgical unit and incised posterior to the enlarged convolutions
- F Dissection is carried out with the suction-coagulation unit. Care is taken to stay within normal tissue well behind the tumor invaded area.
- G The frontal lobe is removed orbital plate and falx are exposed
- H The dura is closed watertight and bone flap replaced A drainage tube is placed in the cavity The scalp is sutured in the usual manner with one layer of end-on interrupted mattress sutures of stainless steel wire.

GLIOMA FRONTAL LOBECTOMY

PINEALOMA

- A Site of tumor dilated lateral ventricle scalp incision.
- B One-inch trephine opening with the lower edge made square with rongeur to the edge of the lateral sinus.
- C Type of dural incision in relation to the lateral sinus needle is inserted into the dilated lateral ventricle for drainage
- D Occipital lobe elevated to the incisura with lighted retractor tentorium incised catheter inserted into the temporal horn through the inferior portion of the temporal occipital lobe.
- E Wedge of tentorium removed for decompression of tumor which is wedged above and below the tentorium

(Continued on Plate 63)

PINEALOMA

F Biopsy of tumor

If the tumor is composed of degenerated tissue it can be readily aspirated. If incomplete extirpation is made, it is necessary to carry out a modified Torkildsen by inserting the distal end of the catheter into the cisterna pontis.

G Site of tumor in relation to the ventricles location of the modified Torkildsen tube.

This tube is of no value if the tumor is of sufficient magnitude to tamponade the lateral cisterns as well as the cisterna pontis. If sufficient space is available for the fluid to flow through the cisterna pontis to the interpeduncular cistern then the tube should be used.

X ray treatment is instituted to the pinealoma as soon as the condition of the patient warrants it.

PINEALOMA

ACOUSTIC NEUROMAS

- A The patient is placed in a sitting position with head slightly flexed incision is shown.

The lateral inferior limb extends approximately 2 cm. below the tip of the mastoid the medial limb ends 2 to 3 cm. below the level of the incision.

- B The muscle is detached from bone with the electrosurgical knife.

- C The mastoid foramen is occluded airtight with wax immediately upon dividing the emissary vein

With the patient in the upright position, it is important that all possible venous spaces be occluded to prevent air embolus. Air may be aspirated into the sinuses through several avenues mastoid foramen emissary vein, larger open veins in the muscle flap, opening in the transverse sinus and the diploic vein in the porous edges of bone.

Multiple burr openings with electric drill simplify bone removal and permit the opening to be made closer to the mastoid cells and transverse sinus. The burr opening above the lateral sinus allows the lateral ventricle to be decompressed by ventricular drainage if obstructive hydrocephalus is present.

ACOUSTIC NEUROMAS

- G Cortical vessels occluded at line of incision
- H Outline of area to be resected.
- I Removal carried out with electrosurgical suction unit.
- J After excision of the lateral portion, the cerebellar hemisphere is elevated medially and cephalad
- K The lower group of cranial nerves, the ninth tenth and eleventh are freed from the inferior medial edge of the tumor and kept protected with a moist cotton pledget.

With the use of urea given intravenously at the start of the operation, excision of the lateral margin of the cerebellar hemisphere is usually unnecessary

(Continued on Plates 67 to 69)

ACOUSTIC NEUROMAS

- L** Arterial vessels over the inferior portion of tumor edge are occluded with the electrosurgical unit a core of tissue is removed with either the electrosurgical knife or the ordinary scalpel.
- M** Intracapsular removal is performed with a pituitary scoop.
- N** Further removal by glass suction care being taken not to injure or penetrate the capsule.
- O** The petrosal vein, as it lies over the superior margin of the capsule, may then be coagulated divided and brushed from the tumor capsule.

In this manner annoying bleeding which may occur if the capsule and vein are retracted from the petrosal sinus can be prevented. The tumor capsule is then elevated from the caudad medial aspect. If adherent to the capsule, the lower cranial nerves must be carefully separated. The posterior inferior cerebellar arterial branch is divided on the capsule after it has been coagulated or divided between clips occlusion of the major vessels must be prevented since this always results in future disability.

Dissection is carried out by placing cotton pledgets on the tumor capsule, and gently brushing the capsule from the cerebellar tissue and pons as the capsule is being retracted downward and the cerebellar hemisphere upward and medially. Great care must be exercised when encountering the site of emergence of the eighth cranial nerve from the pons it is in this area where the seventh cranial nerve may be injured. Usually the seventh nerve is placed anteriorly to the tumor however it may be displaced cephalad and on rare occasions it may be in the caudad position.

As soon as the seventh nerve has been identified, it is separated from the capsule medially and toward the porus acusticus. A cotton pledget is placed over it and dissection carried out from the pontine angle. The fifth cranial nerve is usually distorted to its greatest degree at its junction with the pons. It is also in this region that the plexus of veins is present and must be coagulated on the tumor capsule, divided, and then gently brushed away from the capsule, rather than attempting to coagulate them on the side of the pons. In rare instances the sixth cranial nerve is firmly adherent to the tumor but it is usually displaced medially. For this reason, care must also be instituted at the time the capsule is freed from its most medial anterior portion.

- P** After the bulk of the tumor has been mobilized it is wise to remove the greater bulk, leaving the attachment in the porus acusticus.

(Continued on Plates 68 and 69)

ACOUSTIC NEUROMAS

ACOUSTIC NEUROMAS

- Q** Portion of tumor remaining in the porus acusticus.
- R** Firm, rolled, small cotton pledget inserted into the porus acusticus and firmly pushed into the canal by means of a right-angled nerve hook.
- S** This displaces the tumor and forces it out of the porus acusticus in most instances

If the tumor is inaccessible, it may be necessary to remove the roof of the porus acusticus with mallet and chisel, in order to remove the remaining tissue. Excessive coagulation in the cephalad portion of the porus acusticus is not justifiable, since a slough may occur through the eustachian tube at a later date.

(Continued on Plate 69)

- U** Dural closure.
- V** Closure of scalp with either two layers of interrupted black silk sutures or one layer of interrupted stainless steel wire.
- W** Ventricular and cavity drainage.

After the dressing has been applied the patient is placed in bed in a semisitting position.

ACOUSTIC NEUROMAS

CYSTIC HEMANGIOMA OF THE CEREBELLUM

A Cerebellar hemispheres exposed The right cerebellar hemisphere is enlarged the tonsil in the foramen magnum is depressed more than the left tonsil The solid portion of the tumor is located at the level of the transverse sinus.

B Cystic portion of the tumor drained through a ventricular needle.

This allows the right cerebellar hemisphere to fall away from the tentorium, permitting excision of the tumor over its most dependent portion beneath the tentorium. The solid portion of the tumor is surrounded with the electrosurgical unit, sealing off the entering blood vessels.

C Solid nodule excised The solid portion is sometimes located well beneath the tentorium.

If the fluid is aspirated initially only the superior portion of the cerebellar hemisphere needs to be removed It is always important to incise the most attenuated portion of the cerebellum and attack the tumor through that area.

D Tumor excised cavity

Catheter is inserted into the cavity The dura is left widely open and the usual scalp closure is made with either a layer of interrupted black silk sutures or a single layer of end-on mattress stainless steel wire sutures

(Continued on Plates 71 and 72)

CYSTIC HEMANGIOMA OF THE CEREBELLUM

CYSTIC HEMANGIOMA OF THE CEREBELLUM

Hemangioma with Small Mural Nodule

Widening of the convolutions of the left cerebellar hemisphere the left tonsil is more deeply depressed into the foramen magnum than the right tonsil.

The thinnest portion of the cortex overlying the tumor is incised and opened. It is important to inspect carefully all cystic cavities for a mural nodule. The nodule may be so small that it can be found only by the most minute examination of the cyst wall. This is especially true if there is no external manifestation of the tumor over the cortex.

The mural nodule is excised. It is not necessary to excise a large area of normal tissue. Merely removing the small tumor is sufficient.

(Continued on Plate 7')

CYSTIC HEMANGIOMA OF THE CEREBELLUM

CYSTIC HEMANGIOMA OF THE CEREBELLUM

Hemangioma of Vermis

Illustration of a cystic hemangioma in the midline, with enlargement of the vessels surrounding it, and the mural nodule. The vermis has been split in the midline.

The mural nodule is removed in the usual manner

CYSTIC HEMANGIOMA OF THE CEREBELLUM

SOLID HEMANGIOMA OF THE CEREBELLUM

ASTROCYTOMA OF THE LEFT CEREBELLAR TONSIL

Astrocytomas of the cerebellum may be either cystic or solid. The cystic type with a mural nodule is extirpated in a manner similar to that used in the operation for Cystic Hemangioma of the Cerebellum (Plates 71 and 72)

Astrocytoma involving the tonsil of the left hemisphere and displacing the medulla.

The tonsil is gently elevated and cotton pledgets are inserted over the lower group of cranial nerves. Branches of the posterior inferior cerebellar artery are exposed and divided leaving the main trunk of the artery intact. The tumor should be extirpated completely unless it invades the floor of the fourth ventricle in this instance a thin shell of tumor is left intact.

The dura is left widely open following extirpation and the scalp is closed in the usual manner

ASTROCYTOMA OF THE LEFT CEREBELLAR TONSIL

ANEURYSM OF THE INTERNAL CAROTID ARTERY

- A Operative site type of incision and bone flap
- B For adequate exposure, either the temporal lobe is elevated and the anterior portion of the hippocampal gyrus removed, or the inferior portion of the temporal lobe is excised.
- C Location of aneurysm displacing the posterior communicating artery and also compressing the third cranial nerve. The neck of the aneurysm however is easily accessible, and of such length that a clip may be applied.
- D Aneurysm with the neck slightly submerged, making it impossible to apply a clip accurately
- E If the neck cannot be exposed properly for application of clip, suction is applied to the aneurysm and the aneurysmal wall intentionally ruptured. This allows the aneurysm to enter the glass suction tube, providing adequate exposure of the neck of the aneurysm so that a clip may be accurately applied.

In this particular instance it is wise to occlude temporarily the internal carotid artery immediately beneath the optic nerve, obviating excessive bleeding at the time the clip is applied

- F In most instances the aneurysm itself should not be excised after the clip has been applied. In this particular instance, the aneurysm was excised to demonstrate the marked flattening and depression in the third cranial nerve.

ANEURYSM OF THE MIDDLE CEREBRAL ARTERY

Aneurysm of the middle cerebral artery trunk near the trifurcation.

A Type of incision and bone flap

B Cross section at the level of the aneurysm lying in the sylvian cleft. The temporal lobe, usually immediately in the vicinity of the aneurysm is gliotic. Arachnoidal adhesions protect the aneurysm

C Relative locations of aneurysms on the left and right sides.

D Arachnoidal adhesions are carefully allowed to remain attached to the aneurysm if an attempt is made to separate the adhesions from the aneurysms, rupture will usually occur. The arachnoid is incised well away from the aneurysm, allowing muscle to completely surround the middle cerebral artery and the aneurysm.

E Muscle completely wrapped around the aneurysm and parent vessel.

(Continued on Plate 77)

ANEURYSM OF THE MIDDLE CEREBRAL ARTERY

ANEURYSM OF THE MIDDLE CEREBRAL ARTERY

Saccular aneurysms of the middle cerebral artery associated with intracerebral hematomas.

- F Line of incision over the greatly enlarged superior gyrus of the temporal lobe.
- G Hematoma evacuated silver clip attached to the neck of the aneurysm.
- H Relative positions of aneurysms.
- I In patients with a recent rupture of aneurysm with a large intracerebral hemorrhage in the temporal lobe, aneurysm may rupture at the time of evacuation of the hematoma.
- J Glass suction placed over the area of rupture. The fragmented portion of the aneurysm enters the glass suction tube a silver clip can then be placed at the base of the aneurysm in a dry field

Care must be taken to prevent occlusion of the parent vessel with the silver clip.

Aneurysms at the trifurcation may be treated in a similar manner. If the aneurysm is located on the fronto-orbital or temporal branch of the trifurcation, it may either be excised between clips or simply tacked between clips. Great care must be exercised at all times to save the main trunk of the middle cerebral artery and its branch, the angular artery.

- E Fusiform aneurysmal dilatation of vertebral artery displacing medulla upper cervical cord and lower group of cranial nerves. Silver clip is applied at the point of entrance of the vertebral artery into the spinal canal

COMBINED CERVICAL-CRANIAL PROCEDURE FOR INTRACRANIAL ANEURYSMS

Patients with large subclinoidal parasellar aneurysms may be treated by placing a clamp on the internal carotid artery in the neck. If the patient can tolerate total occlusion of the internal carotid artery for a period of three or four days, a clip is placed on the internal carotid artery intracranially distal to the aneurysm.

Arteriograms will reveal whether a sufficient segment of internal carotid artery is present proximal to the bifurcation of the middle and anterior cerebral arteries.

The incision in the neck is reopened. Immediately following closure of the craniotomy, permanent sutures are placed above and below the segment of the internal carotid artery occluded by the clamp.

Schematic drawing, demonstrating the completed procedure.

Inset: Vestigial type of aneurysm of the internal carotid artery below the bifurcation. The clip occludes the internal carotid artery at the neck of the aneurysm.

This procedure is possible only after determining that the patient can tolerate permanent occlusion of the internal carotid artery. To verify this, a clamp is placed on the internal carotid artery in the neck and left *in situ* for three to four days. See Plate 153.

In this particular instance the clamp may be removed immediately following the craniotomy. It is not necessary to ligate the artery in the neck after removal of the clamp, as would be essential with the trapping procedure.

COMBINED CERVICAL-CRANIAL PROCEDURE FOR
INTRACRANIAL ANEURYSMS

ANGIOMA

A Location of malformation

B Pia-arachnoid coagulated with electrosurgical unit and incised

Care is taken not to enter the larger vessels away from the nidus of the tumor

C Location of nidus of the lesion

D Larger cortical vessels individually isolated away from the nidus and initially occluded by coagulation. The vessels must also be divided between clips, despite apparent occlusion by the electrosurgical unit

Furthermore, the vessels are occasionally too large to be completely occluded by ordinary silver clips. This is obviated by constricting the vessels with coagulation before clips are applied. Usually blood vessel walls are so thin that permanent occlusion with coagulation is impossible.

E Compression of the mass of blood vessels against the falx and the individual ligation and division of arteries as they enter the mass.

It is important to leave draining vessels intact until the end of the procedure. Initial occlusion of these vessels causes rupture of the blood vessel tumor mass because of distention and engorgement.

F The entire mass has been separated from brain tissue and a stalk of the entering blood vessels may be ligated *en masse* either with a ligature of black silk or with a large clip

All bleeding points are carefully controlled.

(Continued on Plate 89)

ANGIOMA

G As soon as the mass of tumor has been removed a large cotton ball is placed in the cavity a large glass suction tip is applied to the cotton ball, and the latter gently elevated. As this is being done the small branches of blood vessels will adhere to the cotton and may be sealed off with the electrosurgical unit coagulation being applied to the end of the vessel that is attached to the cotton rather than to the brain tissue. This allows the sealing off of the small vessels in a dry field.

Removal of these tumors is greatly simplified by use of urea solution intravenously and by the production of mild hypotension during the removal in younger individuals. Hypothermia is not usually necessary.

ANGIOMA

CAROTICOCAVERNOUS SINUS FISTULA

- A · Anatomy of the cavernous sinus system. White circles indicate positions of the rupture of the aneurysm into the cavernous sinus.

The direction of the arterial flow depends greatly upon the size of the aneurysm and the extent to which it has occluded the sinus, as well as upon the exact site of the rupture in the aneurysm—whether it has occurred anteriorly or posteriorly. The presence or absence of pulsating exophthalmos is evident from the drawing.

- B Cross section of normal structures in the cavernous sinus.

- C Fusiform aneurysm, showing compression of the various nerves and obliteration of the greater part of the cavernous sinus.

Treatment consists of ligation of the internal carotid artery in the neck and intracranially distal to the fistula. At times the exophthalmos persists after extracranial and intracranial ligation of the internal carotid artery; this is usually the result of thrombosis of the superior and inferior ophthalmic veins intraorbitally. The exophthalmos may be readily reduced by removing the roof of the orbit and excising the thrombosed veins.

CAROTICOCAVERNOUS SINUS FISTULA

ANTERIOR THIRD VENTRICLE TUMOR

- A Patient placed in Fowler's position with head in vertical flexed position. scalp incision osteoplastic bone flap. location of cyst.
- B A ventricular needle is inserted into the ventricle, either before or after dura is opened, to reduce intraventricular pressure. A transverse cortical incision is made in the anterior portion of the premotor cortex. The relation of the cyst to the foramen of Monro is shown.
- C The ventricle is opened and explored with a lighted retractor on the anterior portion of the incision and a nonlighted malleable retractor on the posterior edge. The tumor can usually be seen immediately at the foramen of Monro.

Fluid should be allowed to remain in the ventricle to prevent collapse of the hemisphere.

ANTERIOR THIRD VENTRICLE TUMOR

COLLOID CYST OF THE THIRD VENTRICLE

- A The capsule of the cyst has been opened to allow aspiration of the gelatinous contents.
- B Gentle traction on the empty cyst wall allows application of a silver clip to the choroid plexus or occlusion of the choroidal vessels with the electrosurgical unit.
- C

Care must be exercised to prevent the blades of the retractors from engaging the brain tissue. The ependyma may be lacerated resulting in subependymal bleeding.

Inset If cyst or tumor does not protrude through the foramen of Monro the septum pellucidum is incised and the anterior third ventricle opened by continuing the incision through the fornices. A catheter maintains ventricular drainage for twenty four hours.

- I Narrow groove made in the bone connecting the two burr openings.
- J Catheter inserted underneath scalp and bone groove.
- K Tip of catheter inserted through ventricular needle opening to the proper depth and sutured to dura.
- L Distal end of catheter cut at proper length.
- M End inserted into cisterna magna. ?
- N Care is taken to be certain that the catheter is open.

(Continued on Plate 100)

OBSTRUCTIVE INTERNAL HYDROCEPHALUS TORKILDSEN
PROCEDURE OF VENTRICULOCISTERNAL DRAINAGE

OBSTRUCTIVE INTERNAL HYDROCEPHALUS TORKILDSEN
PROCEDURE OF VENTRICULOCISTERNAL DRAINAGE

- O Catheter cut at right angle
- P Cut end inserted into the cisterna magna. The dura is closed and the catheter end sutured to the dural edges.
- Q Schematic drawing of site of catheter

As this shows, adequate space must be present in the cisterna pontis to allow fluid from the ventricle to recirculate over the cerebral hemispheres.

OBSTRUCTIVE INTERNAL HYDROCEPHALUS TORKILDSEN
PROCEDURE OF VENTRICULOCISTERNAL DRAINAGE

HYDROCEPHALUS VENTRICULOATRIAL SHUNT WITH HOLTER VALVE

A Sites of incision and location of the Holter valve.

Before surgery x ray films of the chest are taken so that proper measurements can be made from the clavicle to the atrium. The distance from the clavicle to the lower end of the valve can then be measured to obtain the approximate length necessary for the tubing.

Dilute solution of heparin is kept in the tubing at the time of its insertion to prevent clotting and also to prevent air from entering the atrium. The cephalad end of the tubing is kept closed all times until it is attached to the valve. An x ray film is then taken to determine if the end of the tube is in the proper position in the atrium. The valve should be milked just before the lower tubing is attached, to ascertain that the mechanism is working properly.

Care should be taken that a bloodless ventricular tap has been made.

If ventriculography has been performed just before the atrioventricular shunt is instituted, most of the air can be readily removed by inserting physiological saline fluid into the ventricle and allowing the air to escape.

Following surgery the head should be kept toward the side of the shunt to prevent air that might not have escaped following ventriculography from entering the valve. In other words, the head should be kept in the proper position to insure that the end of the ventricular tube is covered with fluid at all times.

(Continued on Plate 102)

HYDROCEPHALUS VENTRICULOATRIAL SHUNT WITH HOLTER VALVE

HYDROCEPHALUS VENTRICULOATRIAL SHUNT WITH HOLTER VALVE

- B Burr opening made in the region indicated in Plate 101 A. A periosteal elevator is used to elevate the scalp between the two incisions to allow insertion of the Holter valve.
- C A director attached to the Holter valve is inserted through the tunnel made under the scalp tissue over the mastoid.
- D Ventricular tube attached to the end of the valve. A small opening is made into the jugular vein or the common facial vein. Polyethylene tubing treated with radiopaque substance is inserted through the opening. A thin wire adapter has been inserted through the tubing to give it stability leaving approximately 1 cm. of tubing extending beyond the tip of the wire guide. (and Simon)

This facilitates guiding the tubing on a direct course into the atrium.

Preoperative Measures

In all major craniotomies the scalp is prepared by shaving immediately before the operation is begun. Preparation is not carried out the evening before surgery because patients are usually annoyed by having their heads clipped and shaved furthermore, the chance of contamination is lower if soap is used generously when the head is shaved immediately preceding the formal preparation of the scalp.

While under general intratracheal anesthesia, the patient is placed in the proper position the position depends entirely on the location of the incision to be made. Intravenous fluids are given through an accessible vein in the lower extremity. To prevent postoperative neck pain excessive rotation of the neck while the patient is under anesthesia should be carefully avoided. No pressure should be exerted over the major vessels of the neck. Compression of the jugular veins, from either the drapes or adhesive tape used to keep the intratracheal tube in position, may well increase engorgement of the cerebral veins.

In the supratentorial craniotomy the patient is placed in exaggerated Fowler's position with the head well above the heart level reducing the intracranial venous pressure.

*Operative Procedure***A** Position of the patient's head for temporal craniotomy

The head is placed on an adjustable head rest and a sandbag or rolled blanket is placed under one shoulder to release the tension on the neck muscles.

B Scalp prepared by thorough washing with soap

Soap is then removed with an alcohol preparation followed by application of colored tincture of Zephiran. Sterile gutta percha is placed over eyes.

C Scalp incision for temporal craniotomy outlined

Towels moistened in aqueous Zephiran solution are applied and sutured to the scalp with silk at strategic points. Moistened towels tend to stay in position better than the dry. Formal draping of the patient is then completed.

D Assistants place the fingers of each hand above and below the line of incision. The surgeon places his thumb over the superficial temporal artery as indicated.

Note that the palmar surfaces of the fingers are used. Assistants are inclined to use the very tips of the fingers, assuming they can exert more pressure in this way.

The incision is made to the surface of the fascia over the temporal muscle and is continued beyond the muscle to the calvarium proper. Hemostats are applied to the galea as indicated with the curved hemostats on the fixed edge of the scalp and the straight hemostats on the flap side of the scalp incision.

(Continued on Plates 104 to 108)

CRANIOTOMY OPENING OSTEOPLASTIC FLAP

CRANIOTOMY OPENING OSTEOPLASTIC FLAP

- E Hemostats on the flap side are retained with a sponge held by an assistant
- F Periosteal elevator used to separate the galea and periosteum from the bone.
- G As the scalp edge is freed, it can be readily reflected from the temporal fascia.

(Continued on Plates 103 to 108)

CRANIOTOMY OPENING OSTEOPLASTIC FLAP

CRANIOTOMY OPENING OSTEOPLASTIC FLAP

- V Line of incision in the dura semicurved incision in the lower portion should correspond to the sylvian fissure anteriorly

In most instances it is not necessary to open the upper line of incision

- W Dura elevated with a dural hook and then incised.
- X Completion of the opening of the dura is made with Metzenbaum scissors.
- Y Lower flap of dura is attached to the temporal muscle, exposing the temporal lobe.

CRANIOTOMY OPENING OSTEOPLASTIC FLAP

CRANIOTOMY CLOSING OSTEOPLASTIC FLAP

A Bone flap separated from muscle tissue, leaving only the periosteum and fascia attached.

This prevents oozing from the bone flap.

Dura is closed with interrupted black silk and a catheter is allowed to remain in the cavity after the temporal lobe or tumor has been removed. The dura is tacked to the edge of the bone or galea this is particularly important on the inferior margin. Small Gelfoam pledgets can be placed under the retaining sutures

B Small drill openings are made in the bone flap at strategic points. Two perforations are made in the denuded portion of the bone flap and a single perforation is made immediately beneath the muscle.

(Continued on Plates 110 to 112)

CRANIOTOMY CLOSING OSTEOPLASTIC FLAP

A

Separating muscle from skull flap
as far as fascial attachment

B

CRANIOTOMY CLOSING OSTEOPLASTIC FLAP

- C Bone flap temporarily replaced to allow accurate markings on the dura corresponding to the perforations.
- D Silk sutures being placed through the dura and bone flap.
- E Closure completed catheter is allowed to emerge through the posterior burr opening and is attached to the scalp with black silk in several figure-of-eight loops.

The purpose of the loops is to prevent the possible escape of the catheter from its position. The more traction placed on the catheter the tighter the silk loops become.

Inset: Dura firmly attached to the bone flap by through-and-through sutures to prevent postoperative extradural clots.

Burr openings in exposed areas of the head are covered with stainless steel wire mesh or tantalum buttons the latter should not be used if silver clips have been used close to the surface or in its immediate surroundings.

(Continued on Plates 111 and 112)

CRANIOTOMY CLOSING OSTEOPLASTIC FLAP

CRANIOTOMY CLOSING OSTEOPLASTIC FLAP

F *a* Scalp flap replaced

b c and d Method of closure with interrupted black silk sutures.

G Alternate method of closure with end-on interrupted stainless steel wire sutures.

This method is used at the present time.

The two ends of wire are grasped approximately 1 cm. from the scalp edge with a hemostat and the hemostat is twisted until proper approximation of the scalp takes place.

(Continued on Plate 112)

CRANIOTOMY CLOSING OSTEOPLASTIC FLAP

F

Scalp flap replaced with scratch-marks in apposition

G

With alternate closure scalp is closed in one layer using wire sutures.

CRANIOTOMY CLOSING OSTEOPLASTIC FLAP

- H Closure completed. A rubber bag with a three-way pet cock with a rubber nipple fastened to one edge is attached to the catheter by means of a blunt 11 gauge needle this permits insertion of a needle, allowing fluid to be removed from the drainage bag without contamination.
- I For adequate protection, cotton must be placed over and behind the ear
This prevents a painful ear resulting from the head bandage, which can occur if the Ace bandage has been applied too snugly
- J Completion of head bandage.

CRANIOTOMY CLOSING OSTEOPLASTIC FLAP

OBTAINING DURAL GRAFT FROM SCALP FLAP

- A Perosteum freed from the scalp flap by inserting the scissors beneath the perosteum.
- B Narrow edge of perosteum allowed to remain on the scalp flap and removal of the perosteal
- C graft completed.
- D Perosteum sutured to the edges of the dura and excess tissue removed.

OBTAINING DURAL GRAFT FROM SCALP FLAP

SUBTEMPORAL DECOMPRESSION

The right side is used for elective subtemporal decompression.

- A Linear slightly oblique incision extends from the zygomatic process to the fascial attachment of the temporal muscle.
- B Area to be removed from the squamous portion of the temporal bone.
- C Scalp incised to fascia covering the temporal muscle. Clamps are placed on the superficial fascia and digital compression on each side of the incision is released. The fascia is incised

A periosteal elevator is inserted in this opening and the temporal muscle elevated so that it can be readily divided with scissors, as demonstrated in the technique for Craniotomy Opening Osteoplastic Flap (Plate 105)
- D The muscle is separated from the squamous portion of the temporal bone with a periosteal elevator the handle of the periosteal elevator is raised to allow insertion of Cushing's subtemporal decompression retractors. Two burr openings are made and the intervening band of bone is removed with rongeur

This facilitates formal removal of bone.

(Continued on Plate 11)

SUBTEMPORAL DECOMPRESSION

SUBTEMPORAL DECOMPRESSION

E Removal of bone in quadrants, starting with segment 1

This simplifies removal of bone, and after the quadrant of bone has been removed bone wax is applied to the bone edge. Segment 2 is removed next, followed by the third and fourth quadrants. Bone from the two lower quadrants is removed to the base of the skull.

The only possible difficulty with bleeding may occur in the region of the pterion. At times the middle meningeal artery lies imbedded and may be torn with the rongeur. This point can be readily controlled by placing a glass suction tip to the point of bleeding, thus allowing the vessel to be occluded with the electrosurgical unit. Bleeding from the bone edge is controlled with wax.

F The dura is opened in segments, following the same rotation as in removal of bone.

G Closure made with several layers of interrupted black silk

H

SUBTEMPORAL DECOMPRESSION

UNILATERAL CEREBRAL ATROPHY HEMISPHERECTOMY

- A Type of incision and bone flap
- B Dura reflected toward the midline atrophic brain
- C Cerebral hemisphere retracted laterally exposing the fronto-polar artery
- D Fronto-polar vessels divided between clips, care being taken to preserve the callosal artery

(Continued on Plates 117 and 118)

UNILATERAL CEREBRAL ATROPHY HEMISPHERECTOMY

UNILATERAL CEREBRAL ATROPHY HEMISPHERECTOMY

- E Sylvian fissure separated. The middle cerebral artery is occluded and divided distal to vessels entering the basal ganglia.
- F Cross section of dilated ventricular system. The middle cerebral artery is divided and penetrating vessels to the basal ganglion spared.
- G The temporo-occipital lobe is now partially elevated to expose the veins of Labbé, which are occluded with the electrosurgical unit and divided.
- H The posterior cerebral artery is exposed by elevating the temporo-occipital lobe and divided between clips as it emerges from the hiatus tentorium.

(Continued on Plate 118)

UNILATERAL CEREBRAL ATROPHY HEMISPHERECTOMY

UNILATERAL CEREBRAL ATROPHY HEMISPHERECTOMY

- E Sylvian fissure separated. The middle cerebral artery is occluded and divided distal to vessels entering the basal ganglia.
- F Cross section of dilated ventricular system. The middle cerebral artery is divided and penetrating vessels to the basal ganglion spared.
- G The temporo-occipital lobe is now partially elevated to expose the veins of Labbé, which are occluded with the electrosurgical unit and divided.

L Skin closure

M Dressing applied.

Tentorial incision or decompression is used in suspected pinealomas. The exploration can be carried out through the same opening and a biopsy taken of the tumor or if it is a degenerated lesion the bulk is aspirated. If a Torkildsen procedure seems necessary refer to Pinealoma (Plates 62 and 63)

DECOMPRESSION OF THE TENTORIAL HIATUS BY INCISION OF THE TENTORIUM

BIMEDIAL PREFRONTAL LOBOTOMY

A Position of head

B Incisions.

With the patient under light Pentothal anesthesia the scalp is infiltrated with 1 per cent procaine in the region in which the incision is to be made. No elaborate measurements are taken since the dimensions of all skulls vary greatly. Visible anatomical landmarks only are used, such as the pupil of each eye and the coronal suture line which is evident after the scalp has been shaved. Two parallel incisions in the sagittal plane, usually 4.0 cm. in length, are made in line with the pupil of each eye, extending just to the anterior border of the coronal suture on each side.

C Scalp edges and periosteum separated with a sharp periosteal elevator

(Continued on Plates 123 to 126)

BIMEDIAL PREFRONTAL LOBOTOMY

C Bone bared with periosteal elevator

BIMEDIAL PREFRONTAL LOBOTOMY

E A ventricular needle is inserted in the direction of the edge of the lesser sphenoid wing, in line with the anterior horn of the lateral ventricle. If the lateral ventricle is normal in size, the needle will just skirt the anterior edge of the anterior horn. If the ventricular system is enlarged as the result of atrophy the ventricular needle may enter the ventricle. It is a simple matter to withdraw the needle and direct it slightly more anteriorly.

F Lateral view of needle in place.

The needle tract serves as a guide both in the location of the ventricle and also for the desired plane of leukotomy. The needle tract is then followed with the electrosurgical suction instrument. After a wedge of cortex has been removed the white tissue is divided by a sweeping motion from side to side.

(Continued on Plates 125 and 126)

BIMEDIAL PREFRONTAL LOBOTOMY

BIMEDIAL PREFRONTAL LOBOTOMY

G The needle tract has been widened.

This procedure is performed under direct vision care being taken that all tiny bleeding vessels are controlled. In most individuals there are few bleeding points in others, however the tiny vessels in the white tissue may be numerous, especially just anterior to the tip of the lateral ventricle.

H Care is taken to be certain that all white tissue is divided on the medial inferior quadrant to the lateral ventricle. Digitations of the white tissue in the gyri are divided under direct vision with the electrosurgical unit, leaving the cortex intact. Incisions made through the white tissue are thoroughly irrigated with saline solution to remove small bits of fragmented brain.

(Continued on Plate 126)

BIMEDIAL PREFRONTAL LOBOTOMY

- I The dura is closed with two interrupted black silk sutures and a hammock of Gelfoam is placed immediately beneath the dural flap. This serves to seal the loosely sewed dura and prevents blood from entering the cranial cavity after operation. Gelfoam is then placed along the edges of the bone, and the bone trephine buttons are replaced.
- J Closure of galea.
- K Scalp is sutured with two layers of interrupted black silk. A light dressing is firmly attached with the elastoplast bandage.

BIMEDIAL PREFRONTAL LOBOTOMY

Closure of galea
over replaced bone
button

Closure of scalp

TEMPORARY CANTHORRHAPHY

Temporary closure of the eyelids is essential to prevent corneal abrasions and excessive hemiation of the edematous conjunctiva. The sutures are placed immediately following the introduction of the anesthetic agent and before formal draping of the patient for orbital decompression.

- A Mattress silk suture inserted through the center of the free edge of the eyelids each loop should emerge at least 4 mm. from the edges.
- B Gutta-percha strip placed beneath each loop of silk as the loop is being tied.
- C Central portion of gutta percha excised to prevent localized pressure necrosis from pressure bandage

2/1

TEMPORARY CANTHORRHAPHY

PERMANENT CANTHORRHAPHY

In rare instances, ulcerations of the cornea resulting from dysfunction of the seventh and fifth cranial nerves must be treated by prolonged closure of the eyelids. This is performed in the following manner

- A Incisions made with a sharp-pointed knife in the free edges of the eyelids.
- B Wedge of tissue removed from the free edges of the eyelids.
- C Mattress sutures inserted through the exact center of the denuded areas.
- D Denuded areas in the free edges of the eyelids are brought together

Great care must be taken while tying the silk sutures to avoid burning the cornea by friction. A piece of gutta percha is inserted under each loop and the silk sutures snugly tied. The eyelashes are left *in situ* and the sutures left in place for seven days. The denuded areas should be firmly united by that time.

If desirable the eyelids can be readily reopened later by dividing the narrow segments of new tissue. At times only canthorrhaphy on the lateral border of the eyelid may be desirable.

When permanent closure in the medial aspect of the eyelid is performed, careful attention must be given to the openings of the lacrimal ducts so that they are not injured.

PERMANENT CANTHORRHAPHY

BILATERAL ORBITAL DECOMPRESSION

- A Modified coronal incision. It is important to make the incision well behind the hair if too close to the hairline, the result is unbecoming until the hair is long enough to hide the scar. In a bald patient, the incision should be made considerably farther post than the well healed incision is not perceptible when the head is in an upright position. If the incision is made in the frontal region it becomes more noticeable.
- B A triangular bone flap is made bilaterally.
- C The bone flap should be broken down as low as possible in the region of the zygomatic bone.
- D The dura is separated from the orbital plate and elevated and the temporal bone removed anteriorly as far as possible.
- E A burr opening is then made over the orbital plate. Usually the roof of the orbit is thin because of intraorbital pressure from the exophthalmos. In many instances a shell is present, in which case it is not necessary to use the electric drill. Care is taken that the orbital fascia is not opened. The roof of the orbit, including the sphenoid wing, is removed with rongeurs.
- F The lateral wall of the orbit can be readily rongeured away after the roof has been removed.

(Continued on Plates 130)

BILATERAL ORBITAL DECOMPRESSION

Alternate lines of incision

BILATERAL ORBITAL DECOMPRESSION

- G** Removal of the inferior portion of the orbital rim with a Kernson punch. If there is an extension of the frontal sinus into the orbital plate (as in Plate 133 C 1) the superior and inferior walls of the sinus are removed and the mucous membrane enfolded and reinforced with Gelfoam, as shown in the postoperative view (Plate 133 C 2) This provides better decompression of the orbital content
- H** The area of incision into the periorbital fascia. The first opening is made along the lower margin (the line marked 1 on the drawing). The anterior portion encircles the lacrimal gland. An opening is next made over the midline (line 2) and then the incision shown as line 3
- I** A lateral view of the field with the first incision about to be started
- J** The remaining strand of fascia is severed (line 4)
- The reason for making the incision in the inferior lateral portion initially is the marked bulging of tissue, which may represent either edematous fat or greatly thickened muscles (see Plate 132, B) The orbital fascia is opened up to the annulus of Zinn. It is preferable not to open the annulus of Zinn since extraocular muscle palsies may occur as a result. The periorbital flaps may be placed over any sinus that is open, however the mucous membrane should be inverted and Gelfoam placed over the opening, then reinforced by laying the orbital fascia or flaps over this.
- K** Demonstration of the bulging, fatty tissue. The bone flaps are replaced and a catheter is inserted through the antero-inferior burr opening.

- C Preoperative and postoperative views. Particular emphasis is placed on the frontal sinus which projects well over the orbital plate at times it (as well as the ethmoid sinuses) may extend for a considerable distance. The upper and lower margins of the sinus walls are removed. Preferably the mucous membrane is kept intact and inverted. If it is not kept intact, it is gently separated with a periosteal elevator imbricated, and reinforced with Gelfoam. The orbital fascia which has been incised is also used to reinforce this.
- D Preoperative and postoperative views of the frontal sinus which is within normal limits. The bone should be removed as close as possible to the frontal sinus however it is not necessary to open the sinus.

CEREBROSPINAL RHINORRHEA SURGICAL TREATMENT

- A With the patient under endotracheal anesthesia and the head extended indigo carmine solution is inserted into the nostril from which the fluid has escaped. If rhinorrhea is bilateral, the solution is injected into each nostril.

Indigo carmine often gives a valuable clue to the location of the fistula after the intracranial exposure has been made.

- B Type of scalp and osteoplastic bone flap The dura is opened in a crescentic single incision.
- C The frontal lobe is elevated and in most instances an obvious defect may be seen. If the condition is longstanding, the arachnoidal adhesions which have formed are separated from the dura.
- D The dura is disengaged from the orbital and cribriform plates. The edge of dura adherent to the bone opening is incised and the dural defect is closed with interrupted black silk.
- E Edges of the bony defect are enlarged with a chisel and then with a rongeur. This allows the mucous membrane to be separated from the sinus, imbricated and reinforced with Gelfoam and muscle.

(Continued on Plates 140 and 141)

SUBOCCIPITAL EXPLORATION (CEREBELLAR EXPLORATION)

PARASAGITTAL CRANIAL EXPLORATION TREPHINE PROCEDURE

At times it is difficult to ascertain from air studies or arteriograms whether a tumor is present and/or the type it is. This is especially true of gliomas in the region of the cingulate gyrus. A satisfactory method which allows a simple exploration through a trephine opening is illustrated. If a tumor is encountered either it may be removed through the trephine opening or the entire outlined incision can be made and a frontal bone flap turned down. If a glioma of the cingulate gyrus extends into the corpus callosum surgery beyond that which can be completed through the trephine opening is superfluous.

IRRITABLE CAROTID SINUS PERIARTERIAL STRIPPING OF CAROTID BULB

INTRACRANIAL ANEURYSM LIGATION OF THE CAROTID ARTERY IN THE NECK

Temporary Application of Carotid Clamp

An oblique cervical incision is made along the anterior surface of the sternocleidomastoid muscle sufficiently high to provide adequate exposure of the bifurcation and internal carotid artery

- A Two loops of heavy black silk are placed around the internal carotid artery approximately 1 cm. apart.
- B Clamp is then placed between the two loops of black silk, close to a point where the internal carotid artery is completely occluded.

Care must be taken not to crush the intima.

- C After careful placement of the clamp, a reading is taken on the clamp scale which has been calibrated in 1 mm. marks.

By this means the degree of closure of the lumen of the artery can be determined, in case the clamp must be opened at a later date.

- D Artery completely occluded by the clamp. A loop of fine silk is placed around the clamp as indicated, to prevent dislocation of the clamp if it is necessary to open it during the trial closure of the artery

At the present time the clamp is applied under general anesthesia. The clamp is left open until the patient is conscious at that time it is closed completely

During the first twenty-four hours after application of the clamp, the patient is watched constantly motor power speech, mental state pulse and blood pressure must be checked every twenty minutes. The nurse must be fully instructed on the procedure of immediately opening the clamp should this become necessary. Close surveillance is maintained for at least three days. If the patient has not tolerated complete occlusion, very gradual occlusion is attempted before closing the clamp 1 mm. each day. If even gradual occlusion is not tolerated, the clamp and the suture material are removed.

If occlusion has been well tolerated and no further procedures are contemplated, small reopenings are made above and below the clamp. Black silk sutures are tied above and below the clamp and the clamp is removed.

If a trapping procedure is to be carried out, permanent ligation of the carotid artery in the neck is performed under the same anesthesia but is not completed until the intracranial portion of the carotid artery is occluded. This lessens the danger of embolus.

INTRACRANIAL ANEURYSM LIGATION OF THE CAROTID ARTERY IN THE NECK

FACIAL PARALYSIS HYPOGLOSSOFACIAL ANASTOMOSIS

- A The incision is made over the anterior edge of the sternocleidomastoid muscle, extending from above the mastoid downward for a distance of approximately 11 to 12.5 cm.
- B The incision is made to the depth of the deep fascia and platysma muscle.
- C Platysma muscle is undermined with Metzenbaum scissors.
- D The fascia and platysma are divided.
- E Hemostats are placed on the edge of the platysma and fascia, uncovering the fascia over the sternocleidomastoid muscle. In the central sketch, the relationship of the various structures is shown for orientation.

(Continued on Plates 155 to 158)

FACIAL PARALYSIS HYPOGLOSSOFACIAL ANASTOMOSIS

FACIAL PARALYSIS HYPOGLOSSOFACIAL ANASTOMOSIS

- A The incision is made over the anterior edge of the sternocleidomastoid muscle, extending from above the mastoid downward for a distance of approximately 11 to 12.5 cm.
- B The incision is made to the depth of the deep fascia and platysma muscle.
- C Platysma muscle is undermined with Metzenbaum scissors.
- D The fascia and platysma are divided.
- E Hemostats are placed on the edge of the platysma and fascia, uncovering the fascia over the sternocleidomastoid muscle. In the central sketch the relationship of the various structures is shown for orientation

(Continued on Plates 155 to 158)

FACIAL PARALYSIS HYPOGLOSSOFACIAL ANASTOMOSIS

- F The sternocleidomastoid muscle is retracted and the cervical fascia opened over the posterior belly of the digastric.
- G The inferior portion of the parotid and the posterior belly of the digastric are exposed.
- H Dissection is carried medially over the tendinous portion of the digastric muscle. Immediately underneath, the hypoglossal nerve can be readily exposed.
- I The descending hypoglossal fibers are separated from the main trunk of the hypoglossal nerve, as indicated by the dotted line. This tends to provide a longer segment of the hypoglossal nerve for mobilization.
- J The hypoglossal nerve is divided at the point where it starts to branch. A tongue depressor is placed immediately beneath the trunk of the nerve so that a clean section can be made with a sharp knife.

(Continued on Plates 156 to 158)

- K The digastric muscle is separated with a periosteal elevator from the fascia overlying the mastoid process.
- L The soft tissues can be separated from the tympanic part of the temporal bone with the periosteal elevator
- M By means of a small, firmly rolled cotton pledget, the soft tissues, including the parotid gland, are pushed upward and medially thus exposing the facial nerve.
- N The facial nerve is divided at the stylomastoid foramen. The nerve hook is allowed to remain around the nerve trunk as the tongue of the parotid gland is elevated upward and medially with a cotton dental roll, exposing the distal cut end of the facial nerve. The central anatomical drawing demonstrates the relationship of the stylomastoid foramen to the tympanic part of the temporal bone and the styloid process

(Continued on Plates 157 and 158)

FACIAL PARALYSIS HYPOGLOSSOFACIAL ANASTOMOSIS

- O** The proximal end of the hypoglossal nerve is brought in contact with the distal end of the facial nerve over the posterior belly of the digastric.
- P** A fine arterial needle is inserted through the central portion of each end of the nerve trunks and the neural sheath is sutured with fine, interrupted black silk arterial sutures. Care must be taken that the nerve ends are not angulated.

(Continued on Plate 158)

FACIAL PARALYSIS HYPOGLOSSOFACIAL ANASTOMOSIS

- Q** The hypoglossofacial anastomosis has been completed. Gelfoam is placed around the line of suture.
- R** Closure of subcutaneous and platysma layers.
- S** Skin closure.

FACIAL PARALYSIS SPINAL ACCESSORY-FACIAL AND PHRENICOFACIAL ANASTOMOSIS

I Spinal Accessory-Facial Anastomosis

- A** Anatomical relationships and completion of anastomosis of the spinal accessory and facial nerves.

II Phrenicofacial Anastomosis

- C** The two lines of incision employed are shown
- D** The phrenic nerve is divided over the lower end of the anterior scalenus muscle.
- E** The proximal end of the phrenic nerve is brought underneath the sternocleidomastoid muscle into the field of the upper incision and the anastomosis made as in the hypoglossal anastomosis.

A combination of a fifth seventh and twelfth cranial nerve paralysis results in drooling and difficulty in mastication. In these patients therefore with a complete fifth and seventh cranial nerve paralysis, either the spinal accessory-facial or phrenicofacial nerve anastomosis is preferable.

In patients whose livelihood depends on singing, elocution and the like, the hypoglossal nerve should not be used. In right-handed patients who have special muscular requirements, for example a symphony orchestra leader if the anastomosis is to be done on the right side, the spinal accessory nerve should not be used—the hypoglossal nerve is preferable.

If bilateral facial nerve paralysis is present, a bilateral hypoglossofacial anastomosis cannot be performed. In such cases the hypoglossofacial anastomosis may be used on one side and a phrenicofacial or spinofacial anastomosis on the opposite side.

FACIAL PARALYSIS SPINAL ACCESSORY-FACIAL AND PHRENICOFACIAL ANASTOMOSIS

I

II

FACIAL PARALYSIS INSERTION OF FACIAL SLING

Support to the face is desirable for patients with facial paralysis when facial tone is expected to return within three months following necessary hypoglossofacial, spinal accessory-facial or phrenicofacial anastomosis

- A Two 1 cm. incisions are made, one at the angle of the mouth and the second over and above the anterior portion of the zygoma.
- B The index finger is inserted into the mouth. A long needle with a stainless steel wire attached is inserted through the zygomatic opening and placed in the tissues as centrally as possible. The needle emerges from the small incision at the angle of the mouth and is then reinserted through this incision.
- C The needle emerges through the small incision over the zygoma.
- D Since it is sometimes difficult to insert the needle through the temporal fascia because of the small incision, a cutting needle is attached to one end of the wire.
- E The needle has been brought through the depth of the fascia and through the skin above the incision.
- F A nerve hook is then inserted underneath the skin to pull the distal end of the wire back through the incision.
- G Wire twisted to obtain the desired length of the sling excess wire cut.
- H Loop in place. The angle of the mouth has been drawn up to a considerable degree, producing a sardonic expression. This is apparent for only a week or ten days, when some relaxation of the angle of the mouth again occurs. The small skin incisions are closed with a single interrupted black silk suture.

FACIAL PARALYSIS INSERTION OF FACIAL SLING

PLATE 160

ANTERIOR SCALENIOTOMY

- A Position of patient.
- B Location of incision relation of incision to clavicle.

Incision should be placed approximately 3 cm. above the clavicle, especially if the patient's head is slightly extended this prevents the incision from falling over the clavicle with head in normal position

- C Platysma muscle separated from underlying tissues by blunt dissection with scissors.
- D Platysma muscle then divided, thus exposing the clavicular portion of the sternocleidomastoid muscle.

(Continued on Plates 162 and 163)

ANTERIOR SCALENIOTOMY

ANTERIOR SCALENIOTOMY

E Section of the clavicular portion of the sternocleidomastoid muscle.

The anterior scalenus muscle can be palpated by inserting a finger to the depth of the incision. This muscle is easily identified by its characteristic contour and it gives a sensation similar to palpating the palmar surface of a thumb.

F Fascia over the anterior scalenus muscle incised

G Phrenic nerve freed from the muscle incorporated in the fascia and retracted medially

At times the phrenic nerve divides into two branches and care must be taken not to divide the accessory branch. When the anterior scalenus muscle is divided on the left side, it is important in this operation to retract medially the fatty tissue lying above the anterior scalenus muscle, to prevent injury to the thoracic duct. If a larger channel of the thoracic duct is divided, the ends should be occluded to prevent future collection of lymph in the operative site.

(Continued on Plate 163)

ANTERIOR SCALENIOTOMY

ANTERIOR SCALENIOTOMY

H Method of incising the anterior scalenus muscle. Bundles of muscle can be readily elevated with a vein retractor and divided with scissors.

I Muscle to be removed, 4 or 5 cm in length

As the muscle fibers are divided cephalad, a corresponding portion of the muscle attached to the first rib should be divided. This prevents retraction of the muscle bundle as a whole, which occurs if the muscle is divided entirely in the upper portion without simultaneous incision in the lower portion.

J Anterior scalenus muscle divided and removed

Fascia of the muscle over the subclavian artery is then divided and the subclavian artery can be freed for adequate decompression. If indicated, the upper branches of the thoracic sympathetic chain are removed as demonstrated in Resection of Cervical Rib and Cervical Sympathectomy (Plate 169)

K Small Penrose drain. Closure of skin as in Resection of Cervical Rib.

RESECTION OF CERVICAL RIB AND CERVICAL SYMPATHECTOMY

A Position of patient.

B Incision.

Refer to the operative technique in Anterior Scaleniectomy for the exposure and resection of the anterior scalenus muscle.

(Continued on Plates 165 to 169)

RESECTION OF CERVICAL RIB AND CERVICAL SYMPATHECTOMY

A

B

C Relationship of the cervical rib to the artery and the lower group of nerves of the brachial plexus.

Removal of the cervical rib is simplified by mobilizing the parietal pleura by incising the Sibson's fascia

(Continued on Plates 166 to 169)

RESECTION OF CERVICAL RIB AND CERVICAL SYMPATHECTOMY

- D Incision of fascia and ligament over tip of cervical rib
- E Ligament excised. Soft tissues removed from the rib with periosteal elevator. Pleura over apex of lung depressed
- F Rib removed piecemeal with rongeur

After the lower portion of the rib has been removed nerve trunks of the brachial plexus can be separated and the rib can be completely removed from the transverse process. The periosteum should be removed with the rib. This procedure usually prevents regeneration.

(Continued on Plates 167 to 169)

RESECTION OF CERVICAL RIB AND CERVICAL SYMPATHECTOMY

RESECTION OF CERVICAL RIB AND CERVICAL SYMPATHECTOMY

H Relationship of rib to artery and brachial plexus.

I Inferior portion of the brachial plexus elevated with light retraction and subclavian artery depressed, thus allowing complete removal of the rib

(Continued on Plate 169)

RESECTION OF CERVICAL RIB AND CERVICAL SYMPATHECTOMY

RESECTION OF CERVICAL RIB AND CERVICAL SYMPATHECTOMY

- J The upper dorsal sympathetic chain should be removed in all patients who have considerable vasomotor changes in the extremity associated with the cervical rib. Usually removal of the second, third and fourth ganglia is sufficient.

The ramus communicans can be separated from the brachial plexus, inferior cervical ganglion and first thoracic ganglion. Care should be exercised not to place too much traction on the stellate ganglion, since a Horner's syndrome will usually develop. If this portion is carefully handled, it is possible to separate the first thoracic ganglion from the inferior cervical ganglion without producing a Horner's syndrome. Thus resection of the first second third and fourth upper thoracic ganglia is completed.

A small Penrose catheter is allowed to remain in the cavity and the incision is closed with interrupted silk sutures. If black silk sutures are used, care must be taken that the subcuticular silk is sufficiently buried so that sutures will not be visible underneath the skin at a later date. For this reason, subcuticular tissues may be closed with fine catgut or cotton.

RESECTION OF CERVICAL RIB AND CERVICAL SYMPATHECTOMY

BRACHIAL PLEXUS NEUROMA EXPOSURE AND REMOVAL

- A Line of incision.
- B Platysma muscle undermined.
- C Incision of platysma muscle.
- D Fascia lateral to the clavicular portion of the sternocleidomastoid muscle freed.
- E Exposure of upper portion of brachial plexus. Clavicle exposed and a section removed.
- F Subclavian and pectoralis minor muscles divided.
- G Exposure of neuroma.
- H Excision of neuroma.

(Continued on Plate 171)

BRACHIAL PLEXUS NEUROMA EXPOSURE AND REMOVAL

BRACHIAL PLEXUS NEUROMA EXPOSURE AND REMOVAL

- I Neuroma compressing the individual nerve fibers. The incision is made over the most attenuated portion.
- J Longitudinal incision
- K Gentle compression of the bulge made by the tumor causes the neuroma to extrude readily. The individual nerve fiber to which the tumor is attached is divided cephalad and caudad.
- L Specimen of neuroma.

SPASMODIC TORTICOLLIS ANTERIOR AND POSTERIOR CERVICAL RHIZOTOMY

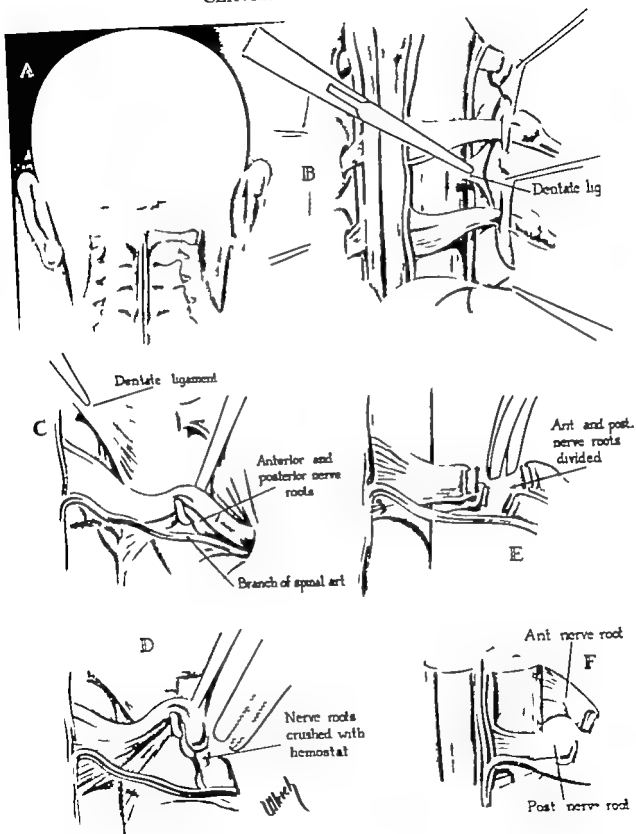

- A Line of incision in the cervical area patient in the upright position Routine laminectomy of the first, second and third cervical laminae is performed.
- B Dentate ligaments divided to allow adequate exposure of the anterior and posterior roots.
- C Division of the nerve roots is begun at the lower portion of the incision (i.e., at the third cervical lamina)
- D First both the anterior and posterior roots are crushed next to the foramen intradurally
- E The roots are divided To prevent ischemia of the upper cervical cord the larger arteries must be carefully preserved
- F Anterior and posterior roots divided artery spared.

The first cervical dermatomes may have only the motor component with no sensory fibers. It is for this reason that separation of the dentate ligaments is of considerable aid.

The spinal accessory branch may be divided on the affected side. I prefer not to section the spinal accessory nerve intraspinally

The dura is closed with interrupted black silk sutures and the soft tissues brought together with a layer of interrupted fine stainless steel sutures or black silk.

SPASMODIC TORTICOLLIS ANTERIOR AND POSTERIOR CERVICAL RHIZOTOMY

SPASMODIC TORTICOLLIS SECTION OF THE STERNOCLEIDOMASTOID MUSCLE

- A Incision over sternocleidomastoid muscle.
- B Muscle tissue freed from fascial bed.
- C Muscle divided at sternoclavicular junction.
- D In this manner the main trunk of the spinal accessory nerve may be left in continuity only the branch innervating the sternocleidomastoid muscle is sacrificed

The spinal accessory nerve occasionally penetrates the muscle in its upper third. It can be readily separated by dividing a few of the fibers of the muscle thus freeing it from its natural bed and allowing it to remain in continuity. It is particularly important to save the main branch of the spinal accessory nerve to prevent a deforming wing scapula.

- E Type of closure to prevent dead space.

A Penrose drain is left in place for a period of twelve to twenty-four hours. A collection of serous fluid can usually be prevented by placing the sutures as indicated, thus obliterating all dead space.

small drain inserted for a period of twenty four hours.

G Dressing.

LUMBAR SYMPATHECTOMY

- A Skin incision is made to correspond approximately to the course of the muscle fibers of the external oblique, 10 to 12 cm. in length the incision extends from the tip of the tenth rib
- B Fibers of the external oblique muscle are split and kept separated with a small saddle retractor
- C Internal oblique muscles are then separated

(Continued on Plates 177 to 180)

LUMBAR SYMPATHECTOMY

LUMBAR SYMPATHECTOMY

- D** Transversalis fibers separated with the blunt portion of the scalpel as far laterally as possible
E to prevent entering the peritoneum.

As soon as the extraperitoneal fat is visualized laterally the index and middle fingers are inserted through the muscle splitting incision. By exerting pressure with the palmar surfaces of those fingers against the parietal surface of the transversalis muscle laterally the line of cleavage can be readily followed. Fingers are slid gently over the inner surface of the quadratus lumborum to the lateral margin of the psoas muscles and then elevated following the contour of the psoas muscle group.

- F** Palmar surfaces of the two fingers lie directly over the psoas muscle group with the peritoneum and its contents displaced medially and upward. Considerable manipulation may be eliminated by inserting a portion of a dental roll attached to a black silk string with long forceps to the site where the palmar surfaces of the index and middle fingers are kept firmly in contact with the muscle group.

Fingers are removed from the site and the cotton roll is kept in contact with the muscle or the forceps.

(Continued on Plates 178 to 180)

LUMBAR SYMPATHECTOMY

LUMBAR SYMPATHECTOMY

G A Grant bladder retractor is inserted by sliding it gently along the forceps to the point where the cotton roll is held on the psoas muscles. This maneuver allows retraction of the peritoneum medially so that the psoas muscles are evident, and also causes the line of reflection of the peritoneum to fold on itself forming a small white line. This line is incised, permitting entry in the proper line of cleavage. Soft tissues are retracted medially to the lateral portion of the bodies of the lumbar vertebrae.

Another Grant bladder retractor is then inserted cephalad well above the attachment of the crus of the diaphragm. The lumbar sympathetic chain and ganglia are evident lying in the gutter formed by the rounded portion of the bodies of the vertebrae and psoas muscles.

(Continued on Plates 179 and 180)

LUMBAR SYMPATHECTOMY

LUMBAR SYMPATHECTOMY

H The sympathetic chain is elevated with a nerve hook and freed from its immediate tissues. The crus of the diaphragm is incised

Removal of the sympathetic trunk in this section is greatly facilitated by division of the ramus before either end of the lumbar chain is divided. The sympathetic chain rarely lies beneath the lumbar vessels on the left side this occurs quite frequently on the right side. At times the vena cava may lie over the sympathetic chain on the right side, but it can be gently retracted. Only if a previous operation has been performed in that area might this be a handicap. In such instances the vena cava may be firmly plastered down by adhesions over the sympathetic trunk.

UPPER THORACIC SYMPATHECTOMY

- A Patient placed on side with shoulder slightly forward
- B To determine the line of incision, the surgeon places his fingers as indicated along the spinous processes, causing the iliocostalis dorsi and longissimus dorsi muscles to bulge. The edge of the trapezius as it crosses these muscles obliquely is outlined in this manner since the bulge of the iliocostalis dorsi and longissimus dorsi is constricted when pressure is exerted in that area. The broken line indicates the lower edge of the trapezius.

The lower end of the incision should extend just beneath the edge of the trapezius, the upper edge to the level of the second rib. The incision is made on the lateral third of the bulge produced by digital compression along the spinous processes, and thus varies in distance from the spinous processes according to thickness of muscle.

- C Fascia over the latissimus dorsi opened immediately beneath edge of trapezius.

This allows insertion of the index finger over the iliocostalis and longissimus muscles cephalad to the first rib. By this maneuver the proper ribs from which a segment is to be removed may be marked. In a round-backed or stoop-shouldered individual, the fourth and sixth ribs may be used to advantage. If the patient has a straight dorsal spine, exposure of the stellate ganglion through the third rib is preferable.

- D Trapezius muscle retracted cephalad.

Usually the trapezius can be retracted sufficiently for adequate exposure of the fourth rib. Occasionally it may be necessary to separate the fibers of the trapezius in their line of cleavage over the third or fourth rib for a more direct approach. Rhomboids are well developed at times and then must be incised.

- E Fascia between iliocostalis dorsi and longissimus dorsi incised immediately over the fourth rib. A periosteal elevator is used to separate the iliocostalis laterally from the rib.
- F Saddle retractor placed underneath the periosteal elevator. Lateral traction is applied and the periosteal elevator removed.
- G Iliocostalis and longissimus dorsi separated over the fourth and sixth ribs.
- H Broad-bladed rounded sharp periosteal elevator (Hedblom) used to separate intercostal muscles from edges of rib.
- I Periosteum separated from rib with a right angle periosteal elevator.

(Continued on Plate 187)

UPPER THORACIC SYMPATHECTOMY

UPPER THORACIC SYMPATHECTOMY

- J** Rounded periosteal elevator inserted under the rib and elevated to allow the lateral margin of the rib to be cut with rib shears. The medial end of the rib is held with a large hemostat the rib is also cut flush with the transverse process medially
- K** Cotton pledget inserted under the medial edge of the rib that has not been excised by rib shears. This portion is removed with rongeurs.
- L** *Parietal pleura separated from attachments. Care must be taken to avoid opening the parietal pleura.*

The lung is depressed with a spatula to allow excision of the stump of the rib

- M** Finger inserted into lateral gutter: parietal pleura gently separated from tissues with a sweeping motion
- N** Relationship of windows made by partial removal of the fourth and sixth ribs.

Parietal pleura cannot be separated for the entire length with the index finger but this facilitates the introduction of a spatula. The remainder of the dissection can be carried out by following the sympathetic trunk to the stellate ganglion. The sympathetic trunk is elevated with a nerve hook as soon as it presents beneath the window made in the fourth rib. Rami communicantes are divided flush with the intercostal nerves however the trunk is not divided throughout the dissection and division of the rami communicantes. The ganglion of the second intercostal nerve is not freed thus rami are left intact. This allows the maneuver as demonstrated in O

- O** Sympathetic trunk rotated around nerve hook. In this manner the first thoracic ganglion can be separated from the inferior cervical ganglion without difficulty

Care must be taken not to place too much traction on the inferior cervical trunk if a more complete denervation is necessary in order to prevent a Horner's syndrome.
The entire stellate ganglion may be removed if necessary

Rami communicantes are divided at the second rib the trunk can be brought down out of the window in the fourth rib. A similar procedure is carried out through the window in the sixth rib leaving rami attached to the fifth and eighth intercostal nerves. This again facilitates division of the rami communicantes at the intervening intercostal nerve. Rami are divided from the uppermost and the lowermost intercostal nerves. The trunk is divided beneath the eighth or ninth rib and is separated from the greater splanchnic nerve.

- P** Closure of deep fascia with interrupted layers of fine stainless steel wire.
- Q** Closure of skin with end-on mattress black silk sutures. A catheter is left in the cavity through the fourth rib until closure is completed

Air collected in the extrapleural space is allowed to escape as the anesthetist increases pulmonary pressure the tube is then pulled out through the closed incision

UPPER THORACIC SYMPATHECTOMY

UPPER THORACIC SYMPATHECTOMY

- J** Rounded periosteal elevator inserted under the rib and elevated to allow the lateral margin of the rib to be cut with rib shears. The medial end of the rib is held with a large hemostat the rib is also cut flush with the transverse process medially

UPPER THORACIC SYMPATHECTOMY

THORACOLUMBAR SYMPATHECTOMY

- B** Visualization of the entire splanchnic distribution from the inside and its relationship to the apertures through which the removal is accomplished.

Inset Separation of ganglion from intercostal vessels before division of the rami communicantes.

The position of the patient during operation is of utmost importance in facilitating the procedure: a lateral semiprone position is used. The longissimus dorsi and iliocostalis dorsi are separated over the medial portion of the eleventh rib as well as over the seventh. The technique used for removing the medial 4 cm. of rib is again the same as that outlined in Upper Thoracic Sympathectomy (Plates 181 and 182).

To prevent deformity the rib should not be removed farther laterally than the width of the iliocostalis dorsi and longissimus dorsi. Removal of as much as possible of the rib vertebrally allows more adequate exposure. Considerable care should be taken to enter the proper line of cleavage between the parietal pleura and the endothoracic fascia. When the line of cleavage has been established, it can be followed medially with a semisharp Hedblom periosteal elevator to the anterolateral border of the vertebral bodies where the greater splanchnic lies.

The index finger is inserted into the space and the line of cleavage followed cephalad and caudad through the openings of the seventh and eleventh ribs. While following the line of cleavage, caution should be exercised to keep the palmar surface of the index finger firmly against the endothoracic fascia rather than against the parietal pleura: this will prevent rupture of the pleura. Even though considerable care has been taken, the pleura may be unintentionally opened; the mere opening of the pleura is not disastrous, and does not cause more than minor difficulties at the time of operation.

After the pleura has been separated paravertebrally cephalad to the level of the fourth thoracic ganglion and caudad to the attachment of the diaphragm, the greater splanchnic nerve is mobilized along its entire course. The greater splanchnic nerve is mobilized first because it lies in a relatively avascular bed.

With the patient in a semiprone position, if slight oozing should occur at the time the ganglia are mobilized and their respective rami divided, blood gravitates toward the mediastinum. If the greater splanchnic were severed after the ganglia had been mobilized, it might be obscured by blood-stained tissue. Great care is taken in mobilizing the nerve fibers making up the greater splanchnic from the individual ganglia. There is considerable difference in the size of the ganglia, and a few may not have individual fibers leading to the greater splanchnic nerve.

After the fourth thoracic ganglion has been mobilized, the trunk is divided above it. The entire mobilized upper sympathetic trunk and its branches are then pulled down through the aperture made by the removal of the eleventh rib. Care is taken to keep the entire system in continuity so that there can be no possibility of leaving ganglia or fibers that lead to the thoracic aorta. To avoid unnecessary bleeding, the thoracic ganglia are carefully separated from the intercostal nerve and artery before dividing the rami. All bleeding, even from a larger intercostal artery can be controlled by the electrosurgical unit.

Dissection of the entire system is less difficult if the thoracic trunk is not divided until the desired number of ganglia to be removed have been mobilized. After the thoracic sympathetic trunk and splanchnic nerve have been completely mobilized in continuity to the diaphragm, the iliocostalis dorsi and longissimus dorsi (which merge into the sacrospinalis at the level of the twelfth rib) are retracted medially toward the spine. This permits incision of the lumbodorsal and transversalis fascia. Care is taken not to injure the iliohypogastric nerve during the dissection. The retroperitoneal space is entered and soft tissues are retracted anteriorly.

The greater splanchnic nerve can be readily identified as it emerges through the diaphragm, usually through a hiatus of its own (as shown in this plate). In some instances it may emerge through the aortic hiatus. The greater and lesser splanchnic nerves usually emerge through the same aperture, but in some patients they emerge through separate apertures in the diaphragm. The greater and lesser splanchnic nerves are then detached from the celiac ganglion. The lesser splanchnic usually has fibers entering the celiac and aorticorenal ganglia. The first, second, and at times the third lumbar ganglia are mobilized, and the sympathetic trunk is divided beneath the third ganglion. The crus of the diaphragm usually covers part of the first lumbar ganglion. With the distal end of the lumbar trunk kept under slight tension, the crus is incised: the first lumbar ganglion is readily exposed and its rami divided.

The incision through the crus of the diaphragm is increased for a distance of several millimeters so that the aperture in the diaphragm is of sufficient size to permit the ganglia to be pulled through it from above. The mobilized cephalad end of the thoracic trunk and the sympathetic nerves are then grasped with forceps. By gentle traction, the subdiaphragmatic portion of the greater and lesser splanchnic, as well as the lumbar sympathetic trunk, can be readily drawn through the diaphragmatic aperture. In this manner the entire system is kept in continuity and there can be no question as to the completeness of the procedure.

THORACOLUMBAR SYMPATHECTOMY

IB

PRESACRAL NEURECTOMY

With the patient under spinal or adequate general anesthesia and in a Trendelenburg position, a midline abdominal incision is made extending 5 to 7 cm. above the umbilicus and carried down two-thirds of the way to the pubis.

The posterior peritoneum is opened exposing the bifurcation of the abdominal aorta. The edges of the posterior peritoneum are separated with black silk sutures as indicated, to allow adequate exposure of the common iliac vessels. The superior hypogastric plexus is exposed by gently brushing the loose connective and lymphatic tissues aside with a cotton pledget. The sympathetic plexus can be seen best as it extends over the bifurcation of the aorta—two large strands with interlacing fibers are usually present.

The best procedure is to elevate the entire plexus *en masse* and divide the connecting smaller strands while dissecting upward over the abdominal aorta for 5 to 7 cm. and then downward along the sacrum. The dissection is simplified by keeping the mass intact at both ends until all intervening communicating fibers have been divided. The main trunks are then severed above and below. All bleeding points are carefully controlled. If lymph channels have been opened, this can be immediately detected by the escape of lymph. These channels are occluded with a ligature of fine black silk or a silver clip. The posterior peritoneum is closed and the usual closure of the abdominal wall is made.

NEUROMA

Exploration, <i>Plates 202 and 203</i>	418-421
--	---------

SURGERY OF THE PERIPHERAL NERVES SCIATIC NERVE AT THE SCIATIC NOTCH

A Line of incision

B Gluteus maximus muscle divided laterally and reflected medially exposing the sciatic nerve trunk at the sciatic notch and the neuroma.

Excision of the neuroma is made as in the operation for Neuromas of the Brachial Plexus and Lumbar Plexus (Plates 171 and 203).

SURGERY OF THE PERIPHERAL NERVES **SCIATIC NERVE AT THE SCIATIC NOTCH**

SURGERY OF THE PERIPHERAL NERVES SCIATIC NERVE

Incision and Exposure

- A If the sciatic nerve is injured or involved with tumor below the sciatic notch, incision is made as indicated.
- B The semitendinosus and biceps femoris muscles are separated, exposing the trunk of the sciatic nerve.

If the sciatic nerve has been lacerated, it is necessary to excise the involved tissue until healthy nerve has been reached. Nerve ends are then brought together as in the operation for Sciatic Nerve at the Sciatic Notch (Plate 186). At times it is necessary to undermine the muscle tissue and free the nerve trunks cephalad and caudad to allow primary suture. Flexion at the knee usually permits excision of a considerable area of the sciatic nerve.

Excision and Suture

- C Laceration of the sciatic nerve trunk with amputation neuromas.
- D Proximal and distal portions of the sciatic nerve dissected and then excised until healthy nerve fibers are visible.
- E Needle inserted through the central portion of the cephalad and caudad sections of the nerve.
- F Sutures inserted through the nerve sheath.
- G The needle which has kept the nerves approximated (in E and F) has been removed and the sutures accurately placed.

SURGERY OF THE PERIPHERAL NERVES SCIATIC NERVE

**SURGERY OF THE PERIPHERAL NERVES EXPOSURE OF THE
COMMON PERONEAL NERVE**

A Line of incision.

B Exposure of the common peroneal nerve just before bifurcation into the deep and superficial branches

SURGERY OF THE PERIPHERAL NERVES EXPOSURE OF THE
COMMON PERONEAL NERVE

SURGERY OF THE PERIPHERAL NERVES EXPOSURE OF THE SURAL NERVE

- A Line of incision.
- B Dotted area approximate area of anesthesia that will develop from section of the sural nerve at the level indicated in A.
- C Sural nerve readily identified, lying in the groove of the gastrocnemius just lateral to the saphena parva vein.

SURGERY OF THE PERIPHERAL NERVES EXPOSURE
OF THE SURAL NERVE

SURGERY OF THE PERIPHERAL NERVES APPROACH TO THE SUPERFICIAL AND DEEP PERONEAL CUTANEOUS BRANCHES

- A A linear incision made approximately 15 cm. above the external malleolus, centering over the line of cleavage between the tibialis anterior and the extensor hallucis longus muscles. Dotted area indicates the area of sensory anesthesia that develops after section of the superficial peroneal nerve at that level
- B Fascia uniting the extensor digitorum longus and extensor hallucis longus is evident and is incised. The superficial peroneal nerve lies on the surface in the line of cleavage of the extensor digitorum longus and extensor hallucis longus
- C Skin retracted medially. The line of cleavage between the extensor hallucis longus and the tibialis anterior is entered. The deep peroneal nerve is easily identified and divided, care being taken not to injure the arteries.
- D Anesthesia that results from division of the deep peroneal nerve dorsally

SURGERY OF THE PERIPHERAL NERVES APPROACH TO THE SUPERFICIAL AND DEEP PERONEAL CUTANEOUS BRANCHES

*Prof. Kohns
Lohr, M.D.*

SURGERY OF THE PERIPHERAL NERVES EXPOSURE OF SAPHENOUS AND POSTERIOR TIBIAL NERVES

- A** Location of incision, about 12.5 cm. above the internal malleolus. Dotted area region in which sensory change takes place following division of the saphenous nerve at this level.
- B** The saphenous nerve lies next to the saphenous vein and is evident lying either over the fascia or in a small septum of the fascia overlying the flexor digitorum longus and soleus muscles.
- A small segment of the nerve is usually excised or may be simply divided with a sharp knife.
- C** Dotted area region of anesthesia
- D** Fascia overlying the flexor digitorum longus and soleus muscles is divided and the line of cleavage between the two muscles is followed to the tibialis nerve. See cross section, F
- In patients with marked ischemia of the foot, it is wise to save the artery that lies in the center of the nerve trunk.
- E** Nerve fibers separated from the artery and divided, leaving the small artery intact.
- F**

SURGERY OF THE PERIPHERAL NERVES EXPOSURE OF SAPHENOUS AND POSTERIOR TIBIAL NERVES

SURGERY OF THE PERIPHERAL NERVES CROSS SECTION OF LOWER THIRD OF LEG AT LEVEL OF NERVE SECTION

This cross section demonstrates the relationship of structures and the line of cleavage that must be followed to reach the individual nerves.

- A Site of incision for exposure of the saphenous nerve and the line of cleavage that must be followed to reach the tibial nerve.
- B Incision for exposure of the superficial peroneal nerve which lies in the fascial groove between the extensor hallucis and extensor digitorum longus muscles.

To expose the deep peroneal nerve, the line of cleavage (dotted line) between the extensor hallucis longus and tibialis anticus muscles can be entered by elevating the subcutaneous tissues.

SURGERY OF THE PERIPHERAL NERVES CROSS SECTION OF LOWER THIRD OF LEG AT LEVEL OF NERVE SECTION

SURGERY OF THE PERIPHERAL NERVES MEDIAN NERVE AT ELBOW

- A Type of incision.
- B Dotted line incision over the fascia and the lacertus fibrosus
- C Exposure of the median nerve and its relationship to the contiguous structures. The dotted line over the fibers of the median nerve indicates the line of incision through the pronator teres when further exposure is necessary

SURGERY OF THE PERIPHERAL NERVES MEDIAN NERVE AT ELBOW

SURGERY OF THE PERIPHERAL NERVES MEDIAN NERVE IN ARM

- A Incision along the medial border of the biceps is made similar to the incision for exposure of the ulnar nerve. The median and ulnar nerves can usually be easily palpated through the skin, and the incision is made accordingly
- B Brachial fascia has been opened and the nerve exposed.
- C Relationship of median nerve to ulnar nerve and traumatic neuroma in continuity

If functioning nerve fibers are still present, treatment is the same as that for neuroma in continuity in the ulnar nerve at the elbow. If no functioning fibers are present, the neuroma is excised as in the operative procedure for laceration of the Sciatic Nerve (Plate 187)

SURGERY OF THE PERIPHERAL NERVES MEDIAN NERVE IN ARM

SURGERY OF THE PERIPHERAL NERVES MEDIAN NERVE AT WRIST

- A Type of incision.
- B Relationship of tissues superficial to the nerve. Dotted line indicates the fascia to be excised over the nerve trunk.
- C Dotted line incision to be made through the transverse carpal ligament if necessary for adequate exposure.

SURGERY OF THE PERIPHERAL NERVES MEDIAN NERVE AT WRIST

SURGERY OF THE PERIPHERAL NERVES MEDIAN NERVE
COMPRESSION AT WRIST (CARPAL TUNNEL SYNDROME)

- A Line of incision
- B Normal relationship of structures.
- C Palmaris longus tendon divided on ulnar side of median nerve. Dotted line line of incision of fascia over median nerve.
- D Freeing of median nerve from transverse carpal ligament.
- E Incision of transverse carpal ligament.
- F Transverse carpal ligament completely divided.

SURGERY OF THE PERIPHERAL NERVES MEDIAN NERVE COMPRESSION AT WRIST (CARPAL TUNNEL SYNDROME)

SURGERY OF THE PERIPHERAL NERVES TRANSPLANTATION OF ULNAR NERVE AT ELBOW

A Line of incision.

B The ulnar nerve is initially exposed above the elbow so that it can be readily followed through the ulnar groove.

It is important to dissect the normal portion of the nerve initially since the fascia overlying the nerve at the elbow proper is usually scarred and firmly adherent to the overlying fascia.

C The nerve, including the traumatic neuroma, has been dissected free.

The skin and subcutaneous tissues are separated from the fascia medially. If normal functioning nerve fibers are present in continuity in the neuroma, the neuroma is excised and the nerve ends reunited.

D A new bed has been made for the nerve for transplantation.

(Continued on Plate 198)

SURGERY OF THE PERIPHERAL NERVES TRANSPLANTATION OF ULNAR NERVE AT ELBOW

SURGERY OF THE PERIPHERAL NERVES TRANSPLANTATION OF ULNAR NERVE AT ELBOW

If functioning nerve fibers are still present in the neuroma in continuity the nerve fibers are decompressed.

E Neuroma in continuity

F Multiple incisions for decompressing nerve fibers.

G Injection of procaine (Novocain) or saline.

SURGERY OF THE PERIPHERAL NERVES TRANSPLANTATION OF ULNAR NERVE AT ELBOW

SURGERY OF THE PERIPHERAL NERVES EXPOSURE OF ULNAR NERVE IN ARM

- A Line of incision on medial aspect of arm.
- B Brachial fascia overlying the nerve divided.
- C Nerve exposed
- D Cross section relationship of structures

SURGERY OF THE PERIPHERAL NERVES EXPOSURE OF ULNAR NERVE IN ARM

SURGERY OF THE PERIPHERAL NERVES EXPOSURE OF
ULNAR NERVE IN ARM

- A Line of incision on medial aspect of arm.
- B Brachial fascia overlying the nerve divided.
- C Nerve exposed.
- D Cross section relationship of structures.

SURGERY OF THE PERIPHERAL NERVES EXPOSURE OF ULNAR NERVE IN ARM

SURGERY OF THE PERIPHERAL NERVES EXPOSURE OF ULNAR NERVE AT WRIST

- A Line of incision
- B Dotted line incision made through the fascia medial to the flexor carpi ulnaris muscle to expose ulnar nerve.
- C Complete traumatic separation of the ulnar nerve. Relationship of contiguous structures. Nerve ends are excised to fresh nerve tissue and resutured.

To obtain adequate length of nerve for anastomosis, it may occasionally be necessary to extend the incision in the forearm. In most instances, however adequate lengthening of the nerve may be obtained by undermining the tissues upward along the course of the nerve itself.

SURGERY OF THE PERIPHERAL NERVES EXPOSURE OF ULNAR NERVE AT WRIST

SURGERY OF THE PERIPHERAL NERVES RADIAL NERVE IN ARM

- A Position of patient and line of incision.
- B Relationship of anatomical structures in the arm
- C Lateral head separated from the long head of the triceps muscle.
- D Exposure of the upper portion of the radial nerve.
- E Old fracture of the humerus.

If a portion of the radial nerve is to be resected because of laceration or neuroma and the ends of the nerve cannot be brought together a portion of the humerus is resected, as indicated by the dotted lines. This allows the radial nerve to be transplanted and the ends brought together by shortening the humerus.

SURGERY OF THE PERIPHERAL NERVES

RADIAL NERVE IN ARM

NEUROMA OF THE LUMBAR PLEXUS EXPLORATION

- A The patient is placed in a slightly oblique position with the hip elevated on the side of the incision. The incision is extended from the tenth rib to the level of the anterior spine of the ilium (refer to Lumbar Sympathectomy Plates 176 to 180).
- B Normal relationship of structures.
- C Index and middle fingers inserted retroperitoneally

A sweeping motion cephalad and caudad along the iliopsoas muscle readily detects a neuroma involving the lumbar plexus even though the neuroma is of small size.

(Continued on Plate 203)

NEUROMA OF THE LUMBAR PLEXUS EXPLORATION

B Normal relationship of structures

C

NEUROMA OF THE LUMBAR PLEXUS EXPLORATION

- D Retroperitoneal operative exposure (refer to Lumbar Sympathectomy Plates 176 to 180)
The iliopsoas muscle is retracted medially and the neuroma exposed
- E Exposure of neuroma by retracting psoas muscle.
- F Longitudinal incision made over the fusiform enlargement of the involved nerve trunk
Slight pressure exerted over the edges of the incision allows the tumor to enucleate itself
- G The entering nerve fibers to the tumor and the emerging nerve fibers are divided allowing the remaining nerve fibers to remain intact The nerve sheath is closed with interrupted fine black silk sutures

For closure of incision, refer to Lumbar Sympathectomy

This approach is used also for the extraspinal portion of dumbbell neurofibromas of the lumbar spinal canal.

INTRAMEDULLARY SPINAL CORD TUMORS

When the surgeon encounters an intramedullary spinal cord tumor he faces a serious decision between removing the tumor or merely performing a decompression by leaving the dura widely open and dividing the dentate ligament.

If the patient is not incapacitated by the tumor or ^Vhas minor symptoms, decompression followed by x ray therapy is the procedure of choice. On the other hand if the patient is greatly incapacitated as the result of tumor if the spinal cord is considerably attenuated dorsally and—furthermore— if the patient and the family have been thoroughly informed of the possible disastrous results from removing the tumor incision of the median raphe of the spinal cord in its most attenuated portion is justified. Whether the tumor has a delineating capsule or whether it cannot be readily separated from the cord can then be determined. If the latter is the case, conservatism is the better part of valor. If however the tumor seems to have a pseudocapsule, enucleation is possible.

Enucleation of an Intramedullary Spinal Cord Tumor

- A Incision over the most attenuated portion.
- B Separation of the inferior margin of the tumor from the spinal cord.
- C By using gentle dissection the tumor can be carefully separated from its tumor bed.
- D Tumor removed, leaving a large cavity in the spinal cord

Bleeding points should be controlled only with small stamps of Gelfoam these are allowed to remain in place until the oozing stops and are then removed.

In the complete removal of an intramedullary tumor the dura should be closed with interrupted black silk. Closure is made with several layers of interrupted black silk or stainless steel wire. I prefer stainless steel wire, especially in the upper dorsal region where considerable traction may be placed on the muscle and skin postoperatively if the patient moves the shoulders vigorously before sufficient healing has taken place.

Postoperative swelling of the spinal cord can be obviated to a considerable degree with the use of urea solutions given intravenously

MENINGIOMAS

Since meningiomas are attached to the dura, [✓]removal of the dura with the tumor is important. Meningiomas posterior to the cord present no particular difficulties except for the vascular dura.

A Silver clips placed along the edge as the dura is incised.

This simplifies the procedure since [✓]the tumor derives all its blood supply from the dural attachment. All bleeding ceases as soon as the involved dura over the tumor has been incised.

B Tumor removed

The dural defect is closed with a dural graft or covered with a thin layer of Gelfoam. If the dura is left open, the muscle must be accurately closed with several layers of interrupted black silk sutures or stainless steel wire. Drainage is not indicated.

(Continued on Plate 206)

MENINGIOMAS

- C** Meningiomas anterior to the cord should be removed piecemeal. After the bulk of the tumor has been removed, sufficient room is usually present to excise the dura that is involved with the tumor. In this instance it is not necessary to repair the dural defect however the dorsal dura is closed watertight.
- D**

At all times caution should be used in the manipulation of the spinal cord in the immediate region of the tumor. All pressure should be exerted away from the cord and never toward it.

MENINGIOMAS

NEUROFIBROMA OF CORD

A Neurofibroma located in the posterior surface of the cord

For all extramedullary tumors a complete laminectomy should be performed covering the area in question this prevents trauma to the spinal cord during the removal of the tumor

The dura is incised well above and below the site of the tumor Small arachnoidal adhesions are freed and the tumor delivered, dividing the nerve fibers that are attached to the upper and lower margins.

B Neurofibroma in the anterolateral portion. Posterior bulging of the spinal cord.

C If small, the tumor may usually be delivered from its bed.

Great care must be taken not to exert pressure on the spinal cord at the time of delivery

✓Removal of the lamina to the pedicle on the side where the tumor is to be delivered often facilitates the operation.

(Continued on Plate 208)

NEUROFIBROMA OF CORD

NEUROFIBROMA OF CORD

D Large neurofibroma anterolateral to the cord

In this particular instance delivery of the tumor without damaging the spinal cord is impossible.

E Dentate ligament divided spinal cord slightly rotated incision made in the capsule of the tumor and intracapsular evacuation performed.

This allows the capsule to be delivered without damage.

At times the tumor is completely obscured anterior to the cord, giving the impression that an intramedullary tumor is present. Dividing the dentate ligament is important, therefore, for thorough inspection of the anterior portion of the cord to ascertain that the tumor is extramedullary

NEUROFIBROMA OF CORD

DUMBBELL NEUROFIBROMA THORACIC REGION

- A Patient in prone position outline of incision location of dumbbell tumor which arises intradurally and extends through the intervertebral foramen to the thoracic area.
- B Cross section dumbbell neurofibroma.

(Continued on Plates 210 to 212)

DUMBBELL NEUROFIBROMA THORACIC REGION

DUMBBELL NEUROFIBROMA THORACIC REGION

- C** Longissimus dorsi muscle divided through a slightly curved incision central portion of the incision is above the spinous processes located over the intradural portion of the tumor

The line of cleavage between the iliocostalis dorsi and longissimus dorsi can always be determined by entering blood vessels

- D** Iliocostalis separated from the longissimus dorsi.

- E** Rib exposed and excised.

For technique of removal refer to Upper Thoracic Sympathectomy (Plates 181 and 182)

(Continued on Plates 211 and 212)

DUMBBELL NEUROFIBROMA THORACIC REGION

DUMBBELL NEUROFIBROMA THORACIC REGION

- F Position of patient relation of incision to spinal cord.
- G Because of the size of the tumor after the intercostal muscle bundle has been divided sections of two ribs are removed medially to expose the parietal pleura and tumor
- H The distal end of the intercostal nerve is divided and the pleura separated from the tumor

(Continued on Plate 212)

DUMBBELL NEUROFIBROMA THORACIC REGION

DUMBBELL NEUROFIBROMA THORACIC REGION

I Removal of tumor in the thoracic area.

J Laminectomy performed, dura opened and intradural portion of tumor exposed

K Tumor removed, leaving a fairly large dural opening.

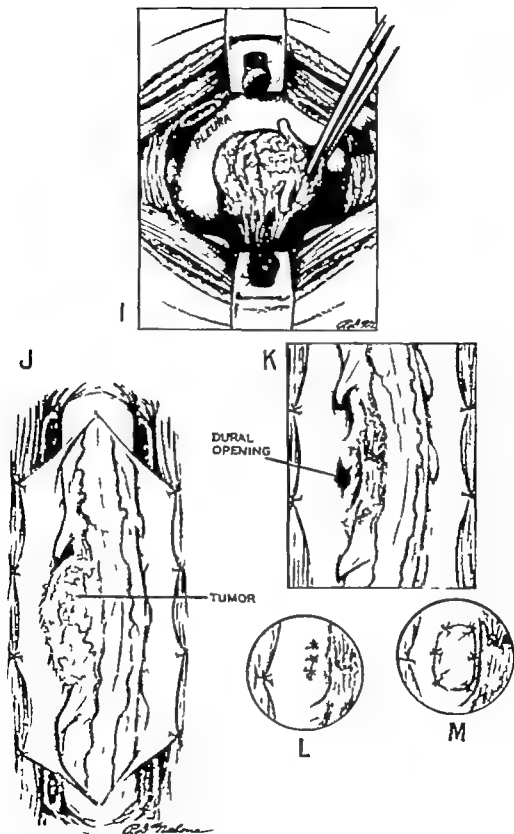

The size of the opening depends entirely on the size of the tumor

L If the opening is small, the dura is sutured from the inside.

M If the opening is too large for simple suture, a dural graft is inserted

The dura is then closed in the usual manner. Closure must be watertight to prevent fluid escaping into the thorax and causing a pseudo-intrathoracic arachnoid cyst.

DUMBBELL NEUROFIBROMA THORACIC REGION

A Ependymoma emerging from the lower end of the spinal cord and extending into the spinal canal

It is important to perform an adequate laminectomy extending well above and below the site of the tumor. At times the tumor can be removed in one segment. In some instances the tumor is soft and adheres to the strands of the cauda equina, thus requiring piecemeal removal. Care is taken not to injure the nerve fibers as the tumor is being removed.

At times it is impossible to remove all the tumor cells. In these cases it is important to follow the operation with x-ray therapy.

B Giant ependymoma extending from the conus medullaris into the sacral canal.

EPENDYMOMA GIANT TUMOR OF THE CAUDA EQUINA

EPIDURAL GRANULOMA, HODGKIN'S DISEASE

Epidural granulomas are usually quite extensive in length before compression of the cord takes place. Removal of the granuloma before complete paralysis occurs is important.

The operative sketch demonstrates an extensive laminectomy. The granuloma is always extradural and can be peeled from the dura. Granulomas rarely extend anterior to the cord and lateral limits are usually at the level of the intervertebral foramina. Opening the dura after removal of the granuloma is unnecessary if normal pulsation takes place. The usual closure is made.

Following recovery from operation x ray therapy is instituted.

In most instances vascular anomalies are extensive and attempted removal can end only in catastrophe. For that reason, a wide laminectomy is performed. The dura is opened, with the incision extending well above and below the involved cord and left widely open for decompression. The usual accurate closure of soft tissues is made and x ray therapy is instituted at a later date.

In rare instances a small aneurysmal varix is uncovered, as shown. If lying superficially the varix may be first occluded by placing a silver clip above and below the sac and then excised. If abnormal vessels are seen above or below the site of the varix very little can be gained by removal of the varix and only decompression is indicated.

VASCULAR ANOMALIES

SACROCOCCYGEAL TUMOR (CHORDOMA GIANT CELL TUMOR, SARCOMA)

The patient is placed in marked Fowler's prone position with thighs flexed.

- A Incision over sacrum and coccyx in midline.
- B Coccyx and lower portion of the sacrum removed. The retrorectal space is opened, exposing the tumor. The tumor capsule is incised and an intracapsular enucleation performed by means of strong suction. Capsule and laminae of the sacrum are removed.
- C Tumor extending through the sacral foramina is removed by aspiration.
- D Relation of tumor to rectosigmoid, coccyx and sacrum.

Catheter is placed in the cavity remaining after tumor is removed. Closure is made with several layers of interrupted black silk sutures.

SACROCOCCYGEAL TUMOR (CHORDOMA GIANT CELL TUMOR SARCOMA)

SYRINGOMYELIA

A Hemilaminectomy over most dependent portion of cyst

B Line of incision over most dependent portion of syninx.

In most instances only the cyst capsule is present, with no vital cord tissue overlying it.

C Dependent portion of cyst more prominent anterior to nerve roots and dentate ligament as occurs occasionally

D Opening through which spinal needle can be readily inserted to aspirate cyst if fluid reaccumulates some months or years later this avoids reopening the incision.

E Fine spinal needle inserted into cyst fluid aspirated

F Acrylic tube inserted into most dependent portion of cyst lower end empties into subarachnoid space.

SYRINGOMYELIA

A Sitting position. Herniation of tonsils through the foramen magnum with compression of the upper cervical cord.

B Removal of bone through a midline incision extending from theasion to the fourth cervical spinous process. Wedging of tonsils into the upper cervical canal.

It is not always necessary to remove the bone over both cerebellar hemispheres. usually removal of the central portion of the occipital bone is sufficient, leaving the dorsal surface of bone over the foramen magnum where it has usually caused considerable constriction.

C Dura is opened widely keeping arachnoid intact.

This prevents the rarely developing arachnoid pseudocyst in the line of incision at a later date.

D If hydromyelia of the upper cervical cord is present, the arachnoid must be opened, tonsils delivered, and the hydromyelic cavity aspirated or opened.

Unless the tonsils are severely scarred and bound down with dense adhesions, resection of the latter is not advisable.

HEMATOMYELIA

Fusiform enlargement of the spinal cord

The posterior median raphe has been incised and the intramedullary clot is being evacuated with suction.

Since considerable edema of the spinal cord is associated with the hematoma, post operative administration of urea solution, given intravenously for two or three days, is important.

SPINAL EPIDURAL ABSCESS

- A Prone position incision.

Incision should extend well above and below the area of the abscess.

- B Cross section compression of the dura and cauda equina by the abscess.

- C Laminectomy drainage of the abscess and removal of most portions of the granulation tissue.

- D Gutta-percha applied to the depth of the incision on the left side, covering all of the soft tissue.

A similar film of gutta percha is placed on the right side.

- E Gauze pack inserted between the layers of the gutta percha to allow adequate drainage and also to prevent premature closure of the incision

The incision is allowed to granulate in slowly from the inside to the outside. Secondary closure of the skin can be made at a later date.

Schematic drawing Dense, thickened arachnoid.

As soon as the arachnoid which has constricted the cord is opened, the blood vessels dilate.

Unfortunately in most instances surgical intervention for arachnoiditis is unsuccessful in relieving the patient's symptoms.

MYELOMENINGOCELE

- A Site of incision.
- B As much as possible of the healthy skin should be saved for closure after repair of the meningocele.
- C Removal of the wedges of skin undermined to the neck of the meningocele.
- D Skin separated from the cyst, keeping the arachnoid intact
- E Sac is inverted

(Continued on Plate 223)

MYELOMENINGOCELE

MYELOMENINGOCELE

F Skin margins are undermined for a considerable distance to allow skin closure and to expose the fascia over the paraspinous muscles

G Rectangular flap of fascia reflected medially from each side.

This tends to bring the muscles together as the two flaps are overlapped.

H Cross section closure.

I Reinforcing the area with multiple layers of interrupted black silk sutures is most important.

At times acute internal hydrocephalus may develop following the procedure. This should be combated either by ventricular drainage or by the use of intravenous urea solution. The internal hydrocephalus subsides in a few days.

MYELOMENINGOCELE

HERNIATED CERVICAL DISK (UNILATERAL)

A Sitting position midline incision.

Exaggerated flexion of the head tends to tighten the paraspinous posterior cervical muscles, increasing the difficulty in traction.

B Method of accurately locating the proper cervical interspace which has previously been determined by myelography. A nerve hook is inserted under the apex of the upper portion of the incision and the index finger is inserted to the second cervical which is always the most prominent. The individual tips of the spinous processes may then be counted as the finger is brought downward.

C Burr openings made over the most lateral portion of the lamina above and below the location of the herniated disk

(Continued on Plates 225 to 227)

HERNIATED CERVICAL DISK (UNILATERAL)

A Sitting position midline incision

Exaggerated flexion of the head tends to tighten the paraspinous posterior cervical muscles, increasing the difficulty in traction.

B Method of accurately locating the proper cervical interspace which has previously been determined by myelography A nerve hook is inserted under the apex of the upper portion of the incision and the index finger is inserted to the second cervical, which is always the most prominent. Soft tissue dissection with
one sweeping movement of broad
bladed periosteal elevator

Ullrich

HERNIATED CERVICAL DISK (UNILATERAL)

- J** Type of perforator and burr used. Opening made in lamina above and below the chosen interspace.

The perforator is used to simplify the insertion of the burr. Care should be taken in using these instruments to avoid injury to the nerve root, which may be firmly compressed against the inferior portion of the lamina. The ligamentum flavum should not be penetrated with either the perforator or the burr. Bony openings may then be enlarged laterally with fine rongeurs.

- K** A simple rupture, without spurring.

- L** Posterior bone lipping or localized traumatic arthritic changes associated with the disk.
M

(Continued on Plate 227)

HERNIATED CERVICAL DISK (UNILATERAL)

HERNIATED LUMBAR DISK (UNILATERAL)

- A Patient placed in the prone position with maximum low back flexion. Short linear incision centered over the spinous processes of the intervertebral spaces involved.
 - B Inferior portion of lamina removed
 - C Unilateral subperiosteal exposure of the lamina above and below the site of the ruptured cartilage. Soft tissues are retracted and depressed with a Hibbs deep-bladed retractor placing tension on tissues that are attached to these lumbar spinous processes
- With this procedure, openings can be made in the fascia over the spinous processes and projections which are occasionally present in the lumbar area can be undercut.
- D Tissues dissected subperiosteally and separated with a sweeping movement of a broad bladed, sharp periosteal elevator
 - E Ligamentum flavum raised with a dural hook and incised longitudinally near the midline.

(Continued on Plates 229 and 230)

HERNIATED LUMBAR DISK (UNILATERAL)

HERNIATED LUMBAR DISK (UNILATERAL)

HERNIATED LUMBAR DISK (UNILATERAL)

- F** Ligamentum flavum incised transversally along the superior margin of the caudad lamina and the inferior margin of the cephalad lamina.

Because of considerable individual variation in normal thickness of the ligamentum flavum as well as variation in the thickness of the epidural fat, care must be taken not to enter the dura.

- G** Free flap of the ligament pulled medially incised at the lateral margin, and carried into the space around the inferior facet. The attachment of the ligamentum flavum can then be separated with a small-bladed knife.

More space is obtained when the ligament is removed in this manner since the thickness of the ligament (at times 2 to 4 mm.) may interfere with the exposure.

- H** After the ligament is removed, the posterior protruding ruptured cartilage can be readily felt by palpation with a forceps, or the nerve root can be seen displaced.

In a few instances the ruptured cartilage has been unintentionally pushed back into its normal position between the bodies of the vertebrae or has receded spontaneously. This is determined by the loss of normal resistance in the posterior longitudinal ligament immediately over the intervertebral space. The surgeon palpating with a forceps, has the impression that only the ligament lies across the space, with no cartilage beneath it.

Care is taken that the point of the forceps is inserted into the gutter of the spinal canal lateral to the nerve root, so that the latter can be readily displaced medially.

- I** A cotton pledget attached to black silk is inserted snugly beneath the cephalad lamina lateral to the nerve root and extradurally. A similar cotton pledget is inserted beneath the caudad lamina and the lateral gutter.

This accomplishes two purposes: the pledgets occlude the epidural vein by pressure above and below the ruptured cartilage, thus avoiding brisk venous oozing; they also tend to keep the nerve root and dural canal displaced medially.

- J** The posterior longitudinal ligament, if not already ruptured, is incised in a rectangular or circular manner between the bodies of the vertebrae. As soon as this has been done, the degenerating cartilage protrudes and at times practically delivers itself. The protruding portion is grasped with pituitary rongeurs and gently teased from the interspace.

At times the entire degenerated portion lies free and is delivered in one large fragmented piece; at other times the torn fragments must be removed piecemeal. With use of the pituitary rongeurs, which have a slight angle, the degenerated portion of cartilage can be removed through a unilateral approach.

- K** Degenerated cartilage removed.

To avoid future herniation, the entire degenerated portion of the cartilage must be removed. In a few patients a definite spurring of the bodies of the vertebrae posteriorly is associated with a ruptured cartilage (refer to Herniated Cervical Disks, Plate 227). Even though the degenerated portion of the disk has been adequately removed, the nerve root is impinged by the proliferation of bone which in reality is a localized traumatic arthritis. These spurs are removed with a chisel as shown in operation for Herniated Cervical Disk.

(Continued on Plate 230)

Plate 229

HERNIATED LUMBAR DISK (UNILATERAL)

HERNIATED LUMBAR DISK (UNILATERAL)

- L** Closure of the subcuticular tissues.
- M** Type of suture used to prevent dead space and collection of serum
- N** Skin closure.
- O** Dressing.
- P** Straight leg maneuver

This is performed immediately following surgery while the patient is still under the influence of the anesthetic agent, in order that the finer adhesions which may have developed in the nerve roots may be released and complete relief from pain hastened. This is especially valuable in patients who have had severe sciatica for a long period of time.

HERNIATED LUMBAR DISK (UNILATERAL)

HERNIATED LUMBAR DISK (CENTRALLY PLACED)

At times a ruptured intervertebral disk is extruded centrally. If removal of the disk through a hemilaminectomy seems impossible without causing undue pressure on a nerve root, a transdural exposure should be made.

- A Dura open bulging of the anterior dura, and enlargement of the nerve root with tiny adhesions.
- B Dura opened and anterior longitudinal ligament incised.
- C Fragmented extruded cartilage removed anterior and dorsal dura closed.

This procedure is necessary only in rare instances but is valuable for patients in whom the extradural approach is impossible.

HERNIATED LUMBAR DISK (CENTRALLY PLACED)

INTRACTABLE PAIN CORDOTOMY

Cordotomy for intractable pain in the lower extremities resulting from metastatic carcinoma or primary malignancy is usually performed in the upper thoracic area however the site of cordotomy varies with the location of the discomfort.

- A Lamina and spinous processes of the third and fourth thoracic vertebrae are removed. If an overhanging spinous process is present in the upper portion, this should be removed, as indicated by the shaded area.
- B Dura opened widely
- C Edges of dura are tacked to the muscle for retraction. The dentate ligament is divided on each side at the level of the cordotomy allowing the cord to be gently rotated

(Continued on Plate 233)

(Continued on Plate 233)

INTRACTABLE PAIN CORDOTOMY

- D** Posterior roots above and below the area of incision in the anterior portion of the cord are divided.

This helps prevent the painful hyperesthesia that may develop postoperatively from traction on the posterior roots.

A cotton pledget is inserted lateral to the spinal cord. By simultaneously exerting very slight pressure on the cotton pledget and elevating the spinal cord by the dentate ligament opposite, the entire anterior quadrant of the cord is readily visualized. Incision with a sharp-pointed knife is started immediately beneath the attachment of the dentate ligament and the entire quadrant is divided, care being taken to prevent injury to the anterior spinal artery.

- E** Rotation of the spinal cord and incision of the entire anterior quadrant.

- F** Bilateral cordotomy

When bilateral cordotomy is necessary, our policy has been to wait a week or ten days before performing the cordotomy on the opposite side.

The incision is then reopened and the cordotomy made one segment below the level of the previous cordotomy.

If the patient has definite bladder incontinence from the original malignancy, the bilateral cordotomy may be performed in one stage. A two-stage operation with an interval of seven to ten days between stages tends to prevent permanent bladder dysfunction.

- G** Cross section of the cord with the anterolateral tracts cut.

The tracts should be divided as close to the midline as is possible without injuring the anterior spinal artery.

INTRACTABLE PAIN CORDOTOMY

INTRACTABLE PAIN POSTERIOR RHIZOTOMY

The usual exposure is made as demonstrated in the technique for laminectomy. The number of laminae to be removed depends on the extent of the segments to be divided. Unilateral laminectomy is sufficient if the pain is on one side.

- A Incision for dorsal rhizotomy
- B Normal relationship of structures.
- C Posterior root easily distinguished from anterior root since it lies dorsal to the dentate ligament.
- D Posterior root carefully separated from the artery. This is most important to prevent ischemia of the spinal cord if extensive rhizotomy is contemplated. Root crushed with hemostat.
- E Spinal artery preserved.
- F Posterior root divided with scissors or scalpel.

The soft tissues are closed with interrupted layers of black silk or stainless steel wire. Stainless steel wire is of particular value if the laminectomy is performed in the upper thoracic region.

INTRACTABLE PAIN POSTERIOR RHIZOTOMY

Part VI NEUROSURGICAL DIAGNOSIS

VENTRICULOGRAPHY <i>Plates 235 236 237</i>	488-493
ENCEPHALOGRAPHY <i>Plates 238 239 240 241</i>	494-501
SINOGRAPHY <i>Plate 242</i>	502-503
PERCUTANEOUS ARTERIOGRAPHY <i>Plates 243 244 245 246</i>	504-511
TURKEL BONE BIOPSY OF SKULL, <i>Plate 247</i>	512-513
SPINAL PUNCTURE, <i>Plate 248</i>	514-515

VENTRICULOGRAPHY

- A** Side view of position of the head.
- B** Posterior view. The incision is 3.0 to 3.5 cm. from the midline, and approximately 7.0 cm. above the level of theinion.
- In most instances the patient has been anesthetized previous to ventriculography and procaine (Novocain) injection is not necessary.
- C** Burr opening made through a small incision. Edges of the scalp are kept separate with a small self retaining retractor.

(Continued on Plates 236 and 237)

VENTRICULOGRAPHY

- D** Dura incised by elevation with a fine dural hook.
- E** Incision enlarged edges readily retracted with light coagulation. A sharp-pointed needle is then inserted through the arachnoid only to allow insertion of the ventricular needle.
- F** Larger cortical veins are usually visible through the dura. If the larger vein traverses the burr opening in its lower margin the dura is opened above to avoid inadvertently opening the vein at the time of dural incision.
- G** At times an aberrant lateral sinus is found immediately beneath the burr opening it can usually be recognized by the bluish cast of the dura.
- H** Burr opening enlarged with rongeur and dura opened lateral to it
- After the dura is opened, the cortex must be inspected for signs of increased pressure.
- I** In this particular instance, the cortex is normal with the sulci of the convolutions of normal width.
- J** Bulging of the cortex and narrowing of the sulci.

(Continued on Plate 237)

E

Cruciate incision of dura

F

Dural incision placed so as to avoid large veins of cortex

G

Abnormal lateral sinus

H

Bone excision extended with rongeur to avoid abnormal sinus

I

Normal appearing cortex

J

Under pressure from tumor cortex bulges when dura is incised

K The left hand is placed over the vertex of the skull, with the middle finger on the bregma and the thumb as shown. The needle is then inserted into the right ventricle through the small opening made in the arachnoid.

L Relation of the needle to the ventricle and the bony opening.

The needle is usually directed toward the upper portion of the eyeball on the side the puncture is made. A ventricular needle is also inserted into the left ventricle. As soon as the ventricle has been entered initially on one side, it is usually preferable to withdraw the needle slightly so that no fluid escapes. A second needle is then inserted into the opposite ventricle, preventing collapse.

M Incision closed with two layers of black silk. Type of suture used to retain catheter which has been inserted through the opening made by the ventricular needle.

Catheter is allowed to remain *in situ* during the operation to permit drainage, and also postoperatively for twenty four to forty-eight hours.

N Type of rubber bag and pet cock attached to catheter for closed drainage.

VENTRICULOGRAPHY

ENCEPHALOGRAPHY

Air studies via the lumbar route are carried out in the x ray department under light Pentothal anesthesia.

Necessary equipment for introduction of air

ENCEPHALOGRAPHY

Patient in a sitting position, supported by adjustable chest and chin bars attached to the side of the x ray table.

(Continued on Plates 240 and 241)

ENCEPHALOGRAPHY

Local infiltration of skin with procaine at either the third or fourth lumbar space.

This allows the 18 gauge spinal needle to be introduced into the subarachnoid space with the patient under light intravenous Pentothal anesthesia. Oxygen or air 15 to 20 cc., is introduced with moderate speed into the subarachnoid space without allowing spinal fluid to escape before the injection

(Continued on Plate 241)

ENCEPHALOGRAPHY

With the patient's head slightly flexed, the oxygen usually fills the fourth ventricle and aqueduct of Sylvius in five seconds. Suitable lateral and posteroanterior films are taken immediately.

The needle is then withdrawn, the patient is placed in the prone position and the routine stereoscopic x ray exposures are made. These include the single anteroposterior posteroanterior views, the right and left lateral views and the brow up and down single views.

If no fluid is allowed to escape, patients tend to have fewer headaches following encephalography and the ventricular filling is more constant. In some instances it may be advantageous to displace most of the cerebrospinal fluid with air or oxygen as in post traumatic syndromes and degenerative diseases. If so, the fluid is allowed to escape in amounts of 5 to 10 cc. and is replaced with air.

SINOGRAPHY

- A Midline incision about 2.5 cm. in length made in the scalp over the sagittal sinus just anterior to the coronal suture.
- B Scalp edge reflected and burr opening made over the central portion of the sagittal sinus.
- C Dural hook inserted into the dorsal roof of the sinus and elevated a small incision is made into the sinus.
- D Catheter inserted, either anterior or posterior
- E Catheter sutured to scalp
- F Incision sutured with two layers of interrupted black silk.
- G Dressing applied A syringe is attached to the catheter and Hypaque or Renografin is injected
Roentgenograms are taken during the injection
- H Pressure exerted over the dressing retaining suture divided and catheter removed.

PERCUTANEOUS ARTERIOGRAPHY

The technique of percutaneous arteriography is simple. The completion of a satisfactory arteriogram depends upon the teamwork of the operator and the x ray technician and upon the physical equipment—namely the x ray apparatus, syringe and needle, which must be in perfect working order.

The patient is allowed to remain on the carrier stretcher and is transported to the x ray department. The wheels of the carriage are firmly fixed so that no motion can occur at the time of injection. Anesthesia is introduced with intravenous Pentothal.

- 3 Care must be exercised to prevent overextension of the patient's neck. It would seem probable that by extension of the neck the large vessels would be held under stretch, thus allowing the needle to enter the lumen more readily. The opposite, however, has been my experience. The lumen of the artery is actually narrowed and may in some instances be occluded by the stretch over the tubercle of the sixth cervical vertebra. The only possible exception is the younger patient in whom the arteries are excessively mobile.

It is important to take frequent blood pressure readings. Contrast medium should not be injected if the blood pressure is materially lowered from the normal or if the patient is anoxicemic.

Equipment necessary for introducing contrast medium (Hypaque or Renografin) into the carotid or vertebral arteries. An 18 gauge needle with a very sharp point and a moderately curved bevel attached to a 10 cc. Luer Lok syringe by a two-way pet cock is used.

(Continued on Plates 244 to 246)

PERCUTANEOUS ARTERIOGRAPHY

| A Towels for draping | H Medicine glasses with Hypaque or Renografin |
| B Sponges | I Gloves with hand towel |
| C Basins with saline (for rinsing syringes) | J 10 cc. syringe |
| D Cup with tincture of Zephiran | K 2 cc. syringe |
| E Cup with 70% alcohol | L Curved arteriogram needles |
| F Extra cup | M Assorted straight needles 26 to 18 gauge |
| G 2.5% sodium citrate | N Two-way pet cocks |

PERCUTANEOUS ARTERIOGRAPHY

- A Positions of the middle finger over the carotid bulb and the index finger over the common carotid artery. The point of the needle has engaged the adventitia and is placed at dead center.
- B Needle in the lumen of the common carotid artery with the bevel pointing laterally toward the lumen of the internal carotid artery.
- C Schematic drawing of the point of the needle in the adventitia.
- D The quick thrust of the needle through the wall.
- E Needle in correct position.

(Continued on Plates 245 and 246)

PERCUTANEOUS ARTERIOGRAPHY

PERCUTANEOUS ARTERIOGRAPHY

The patient's head is allowed to remain in a horizontal plane. The index and middle fingers of the left hand are used to palpate the common carotid artery. The middle finger is placed on the carotid bulb and the index finger on the common carotid artery. The needle is inserted through the skin 1 or 2 cm. above the clavicle and directed cephalad so that the point of the needle engages the adventitia of the common carotid artery immediately beneath the site of the index finger. Delicate pressure is then exerted on the needle with the syringe. The pressure is immediately released if there is any tendency for the artery to roll to one side since this indicates that the point of the needle is engaged eccentrically and not at dead center.

As soon as the operator is certain that the needle is dead center over the artery and that the point is engaged in the adventitia (which must be determined entirely by the feel of the index finger of the left hand and by the sensation transmitted through the needle and syringe to the right hand) the needle may be inserted into the artery by a quick thrust.

(Continued on Plate 246)

PERCUTANEOUS ARTERIOGRAPHY

The left hand is firmly placed over the clavicle, holding the hub of the needle at its attachment to the petal cover. At this time the operator must be certain that the needle is well engaged in the lumen of the artery and will not be displaced by the injection. It is wise to take several practice injections with citrate solution, which is used to prevent clotting of blood in the syringe and needle. If several cubic centimeters can be injected rapidly and a free backflow of arterial blood occurs with the needle directed toward the lateral wall of the common carotid artery, the state is set for the actual injection of the contrast medium. If the arteriogram is to be performed for an aneurysm, 5 cc is usually sufficient for tumors 1 cc is preferable.

Great care must be exercised to prevent bubbles of air which become caught in the hub of the needle as the syringe is attached, from being injected into the carotid system. To prevent this, blood is allowed to flow into the contrast medium so that two or three bubbles of air will be carried to the upper portion of the syringe and remain there during the injection.

A word of caution should be inserted here: the operator and assistant must be careful not to allow themselves to be exposed to radiation beyond the dosage that is safe.

Percutaneous arteriography of the vertebral system is accomplished by inserting the tip of the needle at the level of the cricothyroid cartilage, displacing the carotid artery laterally and introducing the needle at the level of the third or fourth cervical intervertebral foramen. The reason for introducing the needle at this level rather than at the fifth cervical foramen is to prevent a temporary neuritis that may develop in the brachial plexus from irritation of the nerve trunks.

TURKEL BONE BIOPSY OF SKULL

- A Small area of scalp over the lesion is prepared by shaving and infiltrated locally with procaine.
- B Small stab incision.
- C Scalp and outer plate of the calvarium bored through by Turkel perforator
- D The perforator is removed from the hollow cylinder and a needle trephine inserted to obtain a plug of tumor for pathologic study

The Turkel biopsy needle trephine lends itself well to obtaining bone biopsy for suspicious bone tumors, especially of the calvarium

TURKEL BONE BIOPSY OF SKULL

SPINAL PUNCTURE

The diagnostic spinal puncture should be made with the patient in the horizontal position lying on either the right or left side with the lower spine flexed as much as possible. The skin is anesthetized with procaine immediately over the site through which the spinal needle is to be introduced. An 18 or 20 gauge spinal needle is inserted through the skin the point should engage the interspinous ligament at either the third or fourth lumbar space. By gentle advancement the needle is continued on its course through the ligament.

- A The needle has engaged the interspinous ligament between the third and fourth spinous processes.
- B The needle is advanced to the approximate depth of the ligamentum flavum.
- C The stylet is removed a droplet of procaine is inserted into the hub of the needle.
- D The needle is advanced with each thumb placed on the hub as demonstrated in A. As the epidural space is entered, the droplet of procaine can be seen receding into the hub of the needle. As the fluid recedes the spinal manometer is attached to the needle.
- E As the needle with a manometer attached is advanced, the fluid will be seen to rise in the manometer as soon as the subarachnoid space is entered. This is usually 2 to 3 mm. deeper than in C, depending on the thickness of the fatty tissue in the epidural space.

In this manner an accurate pressure reading can be obtained without the loss of spinal fluid. At this time the patient is asked to strain or pressure is made on the abdomen. If the fluid in the manometer rises rapidly the needle is satisfactorily placed.

If the spinal puncture is performed in the presence of an intraspinal lesion, jugular compression is then instituted. On the other hand, if the spinal puncture is performed to determine the intraspinal pressure or the chemistry of the fluid, readings are made and the desired amount of fluid is allowed to escape for examination. *In the detection of a partial spinal block it is important to repeat the jugular compression after the spinal fluid has been removed.* At times a complete or partial block may develop after the removal of the spinal fluid.

- F Sketch demonstrating the possibility of aspirating a nerve root against the needle.

In the removal of Pantopaque or spinal fluid by aspiration, turning the needle or syringe at the time suction is instituted should be avoided to prevent damage to a nerve root. During the removal of Pantopaque a minimal amount of exertion should be used on the piston of the syringe.

SPINAL PUNCTURE

INDEX

A

- Abdomen and chest, procedures affecting, 360-383
- Abscess, epidural spinal, 456-457
- Acoustic nerve, neuromas of 134-145
- Adenoma, pituitary 116-117
- Alcohol injection for trigeminal neuralgia, 10-15
- Aneurysm(s)
 - of anterior cerebral and communicating arteries, 168-171
 - of auditory artery 176-177
 - of bifurcation of internal carotid, middle and anterior cerebral arteries, 162-167
 - crusoid, of scalp 6-9
 - of internal carotid artery 156-157
 - intracranial, 156-181
 - combined cervical-cranial procedure for 180-181
 - ligation of carotid artery in neck for 316-317
 - of middle cerebral artery 158-161
 - of posterior communicating, posterior cerebral and superior cerebellar arteries, 172-173
 - of posterior inferior cerebellar artery 174-175
 - of vertebral artery 178-179
- Aneurysmal varix of spinal cord, 446-447
- Angioma, cerebral, 187-185
- Aranoiditis, cystic localized 458-459
- Arm
 - exposure of median nerve in, 402-403
 - exposure of radial nerve in, 416-417
 - exposure of ulnar nerve in, 414-415
 - peripheral nerves of 400-417
- Arnold-Chiari syndrome, 452-453

- Arterectomy superficial temporal, 38-39
- Arteriography percutaneous, procedure for 504-511
- Arteritis, superficial temporal, arteriectomy for 38-39
- Artery(ies)
 - carotid, internal, aneurysm of 156-157 180-181
 - bifurcation of aneurysm of 167-167
 - thrombosis of endarteriectomy for 308-309
 - ligation of in neck, for intracranial aneurysm, 316-317
 - cerebellar posterior inferior aneurysm of 174-175
 - superior aneurysm of 172-173
 - cerebral, aneurysms of 156-181
 - middle, aneurysm of 158-161
 - communicating, anterior aneurysm of 168-171
 - posterior aneurysm of 168-171
- Astrocystoma of left cerebellar tonsil 154-155
- Atrophy cerebral unilateral hemispherectomy for 240-245
- Auditory artery aneurysm of 176-177

B

- Biopsy bone, of skull, 512-513
- Blepharospasm, facial nerve section for 40-43
- Blood vessels, cerebral procedures affecting, 156-187
- Brachial plexus, neuroma of 350-353
- Brain, procedures affecting, 80-211
- Bulb carotid, periarial stripping of for irritabile carotid sinus, 310-315

- Clinoid, posterior chordoma of 114-115
- meningioma of, 112-113
- Common peroneal nerve, exposure of 390-391
- Communicating artery anterior aneurysm of 168-171
- posterior aneurysm of 172-173
- Convexity meningioma of 86-89
- Cordotomy for intractable pain, 480-483
- Cranial nerves, lower infratentorial section of 278-285
- Cranial procedures, 52-75
- Cranio-pharyngioma, with prefixed chiasm, 122-125
- Craniotomy 214-233
- closing osteoplastic flap, 226-233
- opening osteoplastic flap 214-225
- preoperative measures, 214
- Cribriform plate, meningioma of 92-97
- Cyst, sebaceous, of scalp, removal, 2-3

D

- Decompression, orbital, bilateral, 266-271
- subtemporal, 236-239
- Deep peroneal nerve, approach to, 394-395
- Dental nerve, inferior neurectomy of for trigeminal neuralgia, 24-25
- Diagnosis, neurosurgical, procedures for 488-515
- Disk, intervertebral, herniated, cervical, 464-471
- lumbar 472-479
- Dumbbell neurofibroma of spinal cord, thoracic, 434-441
- Dural graft, obtaining from scalp flap, 234-235

E

- Elbow exposure of median nerve at, 400-401
- transplantation of ulnar nerve at, 408-411
- Encephalography 494-501
- Endarterectomy carotid, for thrombosis, 308-309
- Ependymoma, spinal, 442-443
- Epidural abscess, spinal, 456-457
- Exophthalmos
- due to hyperostosing sphenoid wing meningioma, 106-111

INDEX

Exophthalmos (*Continued*)

- malignant, bilateral orbital decompression for 266-271
 - permanent canthorrhaphy for 264-265
 - progressive, 272-277
 - temporary canthorrhaphy for 262-263
- Exostosis of skull, 52-53
- Extracranial procedures affecting head, 2-49
- Extradural hematoma, 66-69
- Extremities, lower peripheral nerves of 386-399
 - upper peripheral nerves of 400-417
- Eyelids, closure of permanent, 264-265
 - temporary 262-263

F

Facial nerve

- differential section of for facial spasm, 40-43
- paralysis of 318-329
 - hypoglossofacial anastomosis for 318-327
 - insertion of facial sling for 330-331
 - phrenicofacial anastomosis for 328-329
 - spinal accessory-facial anastomosis for 328-329
- Fistula, carotidocavernous sinus, 186-187
- Flap osteoplastic, closing, 226-233
 - opening, 214-225
- Foramen ovale, alcohol injection of for trigeminal neuralgia, 14-15
- Foramen rotundum, alcohol injection of for trigeminal neuralgia, 12-13
- Fracture of skull, depressed comminuted, 62-63
- Frontal lobectomy for glioma, 126-129
- Frontal sinus, osteoma of 44-47

G

- Giant cell tumor sacrococcygeal, 448-449
- Gigli saw use of 220-221
- Glioma, frontal lobectomy for 126-129
 - of optic nerve, 48-49
- Graft, dural, obtaining from scalp flap 234-235
- Granuloma, epidural, spinal, 444-445

H

Head

- injuries to, 62-71
 - procedures affecting, 2-305
 - cranial, 52-75
 - extracranial, 2-49
 - intracranial, 80-211
- Hemangioma of cerebellum cystic, 146-151
 - with small mural nodule, 148-149
 - of vermis, 150-151
 - solid 152-153
- Hematoma, extradural, 66-69
 - subdural 64-65
 - ossified, 70-71
- Hematomyelia, 454-455
- Hemispherectomy for unilateral cerebral atrophy 240-245
- Hiatus, tentorial, decompression of 246-251
- Hodgkin's disease, epidural granuloma due to 444-445
- Holter valve, in ventriculoatrial shunt for hydrocephalus, 208-211
- Hydrocephalus, 194-211
 - anterior third ventriculostomy for 194-199
 - obstructive internal, Torildsen procedure for 200-207
 - ventriculoatrial shunt with Holter valve in, 208-211
- Hypoglossofacial anastomosis for facial paralysis, 318-327
- Hypophysectomy 118-121

I

- Infraorbital nerve, alcohol injection, for trigeminal neuralgia, 10-11
 - neurectomy of for trigeminal neuralgia, 20-23
- Infratentorial section of lower cranial nerves, 278-285
- Intervertebral disk, herniated, cervical, 464-471
 - lumbar 472-479
- Intracranial aneurysm, ligation of carotid artery in neck for 316-317
- Intracranial pressure, subtemporal decompression for 236-239
- Intramedullary spinal cord tumors, 424-425

INDEX

L

- Lacerations of scalp, plastic procedures for 4-5
- Leg, lower third cross section at level of nerve section, 398-399
 - peripheral nerves of 386-399
- Lobectomy frontal, for glioma, 126-129
- Lobotomy bimedial prefrontal 252-261
- Lumbar disk, herniated, 472-479
- Lumbar plexus, neuroma of 418-421
- Lumbar sympathectomy 364-373

M

- Median nerve, compression at wrist, 406-407
 - exposure in arm, 402-403
 - exposure at elbow 400-401
 - exposure at wrist, 404-405
- Meningioma, 80-113
 - of convexity 86-89
 - of cribriform plate, 92-97
 - iceberg type, 90-91
 - large hyperostosing, 80-85
 - of olfactory groove, 92-97
 - parasagittal, 98-105
 - of posterior clinoid and sella turcica, 112-113
 - sphenoid wing, hyperostosing, 106-111
 - spinal, 426-429
 - submerged type, 90-91
- Montenovesi rongeur use of 220-223
- Myelomeningocele, 460-463

N

- Neck, procedures affecting, 308-357
- Nerve(s)
 - acoustic, neuromas of 134-145
 - cranial, lower infratentorial section of 278-285
 - deep peroneal, approach to, 394-395
 - dental, inferior neurectomy of for trigeminal neuralgia, 24-25
 - facial, differential section of for facial spasm, 40-43
 - paralysis of 318-329
 - hypoglossofacial anastomosis for 318-327
 - insertion of facial sling for 330-331
 - phrenico-facial anastomosis for 328-329
 - spinal accessory facial anastomosis for 328-329

Nerve(s) (Continued)

- median, compression at wrist, 406-407
 - exposure in arm, 402-403
 - exposure at elbow 400-401
 - exposure at wrist, 404-405
- optic, glioma of, 48-49
- peripheral, surgery of 386-417
 - arm, 400-417
 - leg, 386-399
- peroneal, common, exposure of 390-391
 - superficial exposure of 398-399
 - superficial and deep approach to 394-395
- radial, exposure in arm, 416-417
- sciatic, surgery of 388-389
- trigeminal, neuralgia of 10-33 See also *Neuralgia trigeminal*
- Neuralgia
 - occipital, neurectomy for 34-37
 - postherpetic, skin excision for 360-363
 - trigeminal, 10-33
 - alcohol injection for 10-15
 - first division, 10-11
 - second division, 12-13
 - third division, 14-15
 - neurectomy for 16-27
 - inferior dental, 24-25
 - infraorbital, 20-23
 - supraorbital, 16-19
 - postherpetic, neurectomy for 26-27
 - sensory root operations for 28-33
- Neurectomy
 - inferior dental, for trigeminal neuralgia, 24-25
 - infraorbital, for trigeminal neuralgia, 20-23
 - occipital, for occipital neuralgia, 34-37
 - preaural, 382-383
 - supraorbital, for trigeminal neuralgia, 16-19
 - postherpetic, 26-27
- Neurofibroma of spinal cord, 430-433
 - dumbbell type, thoracic, 434-441
- Neuroma(s), acoustic, 134-145
 - of brachial plexus, 350-353
 - of lumbar plexus, 418-421

O

- Occipital nerve, neuralgia of neurectomy for 34-37
- Olfactory groove, meningioma of 92-97
- Optic nerve, glioma of 48-49
- Orbicularis oculi, spasm of facial nerve section for 40-43
- Orbit, tumors of 48-49

Orbital decompression, bilateral, 266-271
 Osteoma of frontal sinus, 44-47
 of skull, 52-53
 Oxycephaly 54-55

P

Pain, intractable, cordotomy for 480-483
 posterior rhizotomy for 484-485
 Paralysis, facial, 318-329
 hypoglossofacial anastomosis for 318-327
 insertion of facial sling for 330-331
 phrenicofacial anastomosis for 328-329
 spinal accessory-facial anastomosis for 328-329
 Parasagittal cranial exploration, 304-305
 Peripheral nerves, surgery of 386-417
 arm, 400-417
 leg, 386-399
 Peroneal nerve, common, exposure of 390-391
 superficial, exposure of 398-399
 superficial and deep approach to 394-395
 Phrenicofacial anastomosis for facial paralysis, 328-329
 Pinealoma, 130-133
 Pituitary removal of 118-121
 tumors of 116-125
 chromophobe and chromophil, 116-117
 Platybasia, 452-453
 Plexus, lumbar neuroma of 418-421
 Pneumoencephalography procedure for 494-501
 Posterior tibial nerve, exposure of 396-397
 Postherpetic neuralgia, skin excision for 360-363
 Prefrontal lobotomy bimedial, 252-261
 Presacral neurectomy 382-383
 Puncture, spinal, procedure for 514-515

R

Radial nerve, exposure in arm, 416-417
 Rathke's pouch tumor 122-125
 Rhinorrhea, cerebrospinal, 286-291
 Rhizotomy cervical anterior and posterior for
 spasmodic torticollis, 354-355
 posterior for intractable pain, 484-485
 Rib, cervical, resection of 338-349

S

Sacrococcygeal tumors, 448-449
 Sagittal sinus, meningioma involving, 98-105
 Saphenous nerve, approach to 396-397
 exposure of 398-399
 Sarcoma, sacrococcygeal 448-449
 Scaleniectomy anterior 332-337
 Scalenus, anterior syndrome, scaleniectomy for 332-337
 Scalp
 cirsoid aneurysm of 6-9
 closing, procedure for 226-233
 lacerations of plastic procedures for 4-5
 obtaining dural graft from, 234-235
 opening, procedure for 214-225
 sebaceous cyst of removal, 2-3
 Scaphocephaly 56-57
 Sciatic nerve, surgery of 388-389
 Sebaceous cyst of scalp, removal 2-3
 Sella turcica, chordoma of 114-115
 meningioma of 112-113
 Shunt, ventriculoatrial, with Holter valve for hydrocephalus, 208-211
 Sinography procedure for 502-503
 Sinus
 carotid, irritable, stripping of carotid bulb for 310-315
 cavernous, fistula with carotid artery 186-187
 frontal osteoma of 44-47
 repair of for cerebrospinal rhinorrhea 290-291
 sagittal, meningioma involving, 98-105
 Skull
 exostosis of 52-53
 fracture of depressed comminuted 62-63
 plastic procedures on, 58-61
 procedures affecting, 52-75
 Tutkel bone biopsy of 512-513
 Sling, facial, for facial paralysis, 330-331
 Spasm, facial, nerve section for 40-43
 Sphenoid wing, meningioma of hyperostosing, 106-111
 Spinal accessory-facial anastomosis for facial paralysis, 328-329
 Spinal cord
 congenital defect of 460-461
 tumors of 424-449
 dumbbell neurofibroma, thoracic region, 434-441
 ependymoma, 442-443

INDEX

L

- Lacerations of scalp plastic procedures for 4-5
- Leg, lower third cross section at level of nerve section, 398-399
- peripheral nerves of 386-399
- Lobectomy frontal, for glioma, 126-129
- Lobotomy bimodal prefrontal, 252-261
- Lumbar disk, herniated, 472-479
- Lumbar plexus, neuroma of 418-421
- Lumbar sympathectomy 364-373

M

- Median nerve, compression at wrist, 406-407
 - exposure in arm, 402-403
 - exposure at elbow 400-401
 - exposure at wrist, 404-405
- Meningioma, 80-113
 - of convexity 86-89
 - of cribriform plate, 92-97
 - iceberg type, 90-91
 - large hyperostosing, 80-85
 - of olfactory groove, 92-97
 - parasagittal, 98-105
 - of posterior clinoid and sella turcica, 112-113
 - sphenoid wing, hyperostosing, 106-111
 - spinal, 426-429
 - submerged type, 90-91
- Montenovesi rongeur use of 220-223
- Myelomeningocele, 460-463

N

- Neck, procedures affecting, 308-357
- Nerve(s)
 - acoustic, neuromas of 134-145
 - cranial, lower infratentorial section of 278-285
 - deep peroneal approach to 394-395
 - dental inferior neurectomy of for trigeminal neuralgia, 24-25
 - facial, differential section of for facial spasm, 40-43
 - paralysis of 318-329
 - hypoglossofacial anastomosis for 318-327
 - insertion of facial sling for 330-331
 - phrenicofacial anastomosis for 328-329
 - spinal accessory-facial anastomosis for 328-329

Nerve(s) (Continued)

- median, compression at wrist, 406-407
 - exposure in arm, 402-403
 - exposure at elbow 400-401
 - exposure at wrist, 404-405
- optic, glioma of 48-49
- peripheral, surgery of 386-417
 - arm, 400-417
 - leg, 386-399
- peroneal common, exposure of 390-391
 - superficial, exposure of 398-399
 - superficial and deep, approach to, 394-395
- radial, exposure in arm, 416-417
- sciatic, surgery of 388-389
- trigeminal, neuralgia of 10-33 See also *Neuralgia trigeminal*
- Neuralgia
 - occipital, neurectomy for 34-37
 - postherpetic, skin excision for 360-363
 - trigeminal, 10-33
 - alcohol injection for 10-15
 - first division, 10-11
 - second division, 12-13
 - third division, 14-15
 - neurectomy for 16-27
 - inferior dental, 24-25
 - infraorbital, 20-23
 - supraorbital, 16-19
 - postherpetic, neurectomy for 26-27
 - sensory root operations for 28-33
- Neurectomy
 - inferior dental, for trigeminal neuralgia, 24-25
 - infraorbital, for trigeminal neuralgia, 20-23
 - occipital, for occipital neuralgia, 34-37
 - presacral, 382-383
 - supraorbital, for trigeminal neuralgia, 16-19
 - postherpetic, 26-27
- Neurofibroma of spinal cord 430-433
 - dumbbell type, thoracic, 434-441
- Neuroma(s), acoustic, 134-145
 - of brachial plexus, 350-353
 - of lumbar plexus, 418-421

O

- Occipital nerve, neuralgia of neurectomy for 34-37
- Olfactory groove, meningioma of 92-97
- Optic nerve, glioma of, 48-49
- Orbicularis oculi, spasm of facial nerve section for 40-43
- Orbit, tumors of 48-49

INDEX

Orbital decompression, bilateral 266-271
 Osteoma of frontal sinus, 44-47
 of skull, 52-53
 Oxycephaly 54-54

P

Pain, intractable, cordotomy for 480-483
 posterior rhizotomy for 484-485
 Paralysis, facial, 318-329
 hypoglossofacial anastomosis for 318-327
 insertion of facial sling for 330-331
 pharyngeofacial anastomosis for 328-329
 spinal accessory facial anastomosis for 328-329
 Parasagittal cranial exploration, 304-305
 Peripheral nerves, surgery of 386-417
 arm, 400-417
 leg, 386-399
 Peroneal nerve, common, exposure of 390-391
 superficial, exposure of 398-399
 superficial and deep approach to, 394-395
 Pharyngeofacial anastomosis for facial paralysis, 328-329
 Pinealoma, 130-133
 Pituitary removal of 118-121
 tumors of 116-125
 chromophobe and chromophil, 116-117
 Platybasia, 452-453
 Plexus, lumbar neuroma of 418-421
 Pneumoencephalography procedure for 494-501
 Posterior tibial nerve, exposure of 396-397
 Postherpetic neuralgia, skin excision for 360-363
 Prefrontal lobotomy bimedial 252-261
 Presacral neurectomy 382-383
 Puncture, spinal, procedure for 514-515

R

Radial nerve, exposure in arm, 416-417
 Rathke's pouch tumor 122-125
 Rhinorrhea, cerebrospinal, 286-291
 Rhizotomy cervical, anterior and posterior for
 spasmodic torticollis, 354-355
 posterior for intractable pain, 484-485
 Rib cervical resection of 338-349

S

Sacrococcygeal tumors, 448-449
 Sagittal sinus, meningioma involving, 98-105
 Saphenous nerve, approach to 396-397
 exposure of 398-399
 Sarcoma, sacrococcygeal, 448-449
 Scaleniectomy anterior 332-337
 Scalenus, anterior syndrome, scaleniectomy for 332-337
 Scalp
 cirsoid aneurysm of 6-9
 closing, procedure for 226-233
 lacerations of plastic procedures for 4-5
 obtaining dermal graft from, 234-235
 opening, procedure for 214-225
 sebaceous cyst of removal, 2-3
 Scaphocephaly 56-57
 Sciatic nerve, surgery of 388-389
 Sebaceous cyst of scalp, removal 2-3
 Sella turcica, chordoma of 114-115
 meningioma of 112-113
 Shunt, ventriculoatrial, with Holter valve, for hydrocephalus, 208-211
 Sinography procedure for 502-503
 Sinus
 carotid irritable, stripping of carotid bulb for 310-315
 cavernous, fistula with carotid artery 186-187
 frontal, osteoma of 44-47
 repair of for cerebrospinal rhinorrhea, 290-291
 sagittal meningioma involving, 98-105
 Skull
 exostosis of 52-53
 fracture of depressed comminuted, 62-63
 plastic procedures on, 58-61
 procedures affecting, 52-75
 Turkeltaub biopsy of 512-513
 Sling, facial, for facial paralysis, 330-331
 Spasm, facial, nerve section for 40-43
 Sphenoid wing, meningioma of hyperostosing, 106-111
 Spinal accessory-facial anastomosis for facial paralysis, 328-329
 Spinal cord
 congenital defect of 460-461
 tumors of 424-449
 dumbbell neurofibroma, thoracic region, 434-441
 ependymoma, 442-443

INDEX

L

- Lacerations of scalp, plastic procedures for 4-5
- Leg, lower third cross section at level of nerve section, 398-399
 - peripheral nerves of 386-399
- Lobectomy frontal, for glioma, 126-129

- Neuroma(s), acoustic, 134-145
 - of brachial plexus, 350-353
 - of lumbar plexus, 418-421

O

- Occipital nerve, neuralgia of neurectomy for 34-37
- Olfactory groove, meningioma of 92-97
- Optic nerve, glioma of 48-49
- Orbicularis oculi, spasm of facial nerve section for 40-43
- Orbit, tumors of, 48-49

Orbital decompression bilateral, 266-271
 Osteoma of frontal sinus, 44-47
 of skull, 52-53
 Oxycephaly 54-55

P

Pain, intractable, cordotomy for 480-483
 posterior rhizotomy for 484-485
 Paralysis, facial, 318-329
 hypoglossofacial anastomosis for 318-327
 insertion of facial sling for 330-331
 phrenicofacial anastomosis for 328-329
 spinal accessory-facial anastomosis for 328-329
 Parasagittal craniol exploration, 304-305
 Peripheral nerves, surgery of 386-417
 arm, 400-417
 leg, 386-399
 Peroneal nerve, common, exposure of 390-391
 superficial, exposure of 398-399
 superficial and deep, approach to, 394-395
 Phrenicofacial anastomosis for facial paralysis, 328-329
 Pinealectomy, 130-133
 Pituitary removal of 118-121
 tumors of, 116-125
 chromophobe and chromophil, 116-117
 Platybasia, 452-453
 Plexus, lumbar neuroma of 418-421
 Pneumoencephalography procedure for 494-501
 Posterior tibial nerve, exposure of 396-397
 Postherpetic neuralgia, skin excision for 360-363
 Prefrontal lobotomy bimedial, 252-261
 Presacral neurectomy 382-383
 Puncture, spinal, procedure for 514-515

R

Radial nerve exposure in arm, 416-417
 Rathke's pouch tumor 122-125
 Rhinorrhea, cerebrospinal, 286-291
 Rhizotomy cervical, anterior and posterior for
 spasmodic torticollis, 354-355
 posterior for intractable pain 484-485
 Rib, cervical resection of 338-349

Sacrococcygeal tumors, 448-449
 Sagittal sinus, meningioma involving, 98-105
 Saphenous nerve, approach to, 396-397
 exposure of 398-399
 Sarcoma, sacrococcygeal, 448-449
 Scalenotomy anterior 332-337
 Scalenus, anterior syndrome, scalenotomy for 332-337
 Scalp
 cirsoid aneurysm of 6-9
 closing, procedure for 226-233
 lacerations of plastic procedures for 4-5
 obtaining dural graft from, 234-235
 opening, procedure for 214-225
 sebaceous cyst of removal, 2-3
 Scaphocephaly 56-57
 Sciatic nerve, surgery of 388-389
 Sebaceous cyst of scalp removal, 2-3
 Sella turcica, chordoma of 114-115
 meningioma of 112-113
 Shunt, ventriculoatrial, with Holter valve, for
 hydrocephalus, 208-211
 Sinography procedure for 502-503
 Sinus
 carotid irritable, stripping of carotid bulb for 310-315
 cavernous, fistula with carotid artery 186-187
 frontal, osteoma of 44-47
 repair of for cerebrospinal rhinorrhea, 290-291
 sagittal, meningioma involving, 98-105
 Skull
 exostosis of 52-53
 fracture of depressed comminuted, 62-63
 plastic procedures on, 58-61
 procedures affecting, 52-75
 Turkeli bone biopsy of 512-513
 Sling, facial, for facial paralysis, 330-331
 Spasm, facial, nerve section for 40-43
 Sphenoid wing, meningioma of hyperostosing, 106-111
 Spinal accessory-facial anastomosis for facial paralysis, 328-329
 Spinal cord
 congenital defect of 460-461
 tumors of 424-449
 dumbbell neurofibroma, thoracic region, 434-441
 ependymoma, 442-443

INDEX

Spinal cord, tumors of (*Continued*)
 epidural granuloma, 444-445
 extramedullary 430-433
 intramedullary 424-425
 meningiomas, 426-429
 neurofibroma, 430-433
 sacrococcygeal, 448-449
 vascular anomalies of 446-447
 Spinal puncture, procedure for 514-515
 Spine, procedures affecting, 424-485
 Sternocleidomastoid muscle, section, for spasmodic torticollis, 356-357
 Subdural hematoma, 64-65
 ossified, 70-71
 Suboccipital exploration, 292-303
 Suboccipital operative procedures, 134-145
 Subtemporal decompression, 236-239
 Superficial peroneal nerve, approach to, 394-395
 exposure of 398-399
 Supraorbital nerve, alcohol injection, for trigeminal neuralgia, 10-11
 neurectomy for postherpetic trigeminal neuralgia, 26-27
 for trigeminal neuralgia, 16-19
 Sural nerve, exposure of 392-393
 Sutures, cranial, premature closure of 54-57
 Sympathectomy
 cervical, in cervical rib syndrome, 348-349
 lumbar 364-373
 thoracolumbar 378-381
 upper thoracic, 374-377
 Synostosis cranii, 54-57
 Syringomyelia, 450-451

T

Temporal arteritis, superficial, arteriectomy for 38-39
 Tentorium, hiatus of aneurysms at, 172-173
 incision of for decompression of tentorial hiatus, 246-251
 Thoracic sympathectomy upper 374-377
 Thoracolumbar sympathectomy 378-381
 Tibial nerve, approach to, 398-399
 posterior exposure of 396-397
 Tic, facial spasmodic, facial nerve section for 40-43
 Tonsil, cerebellar astrocytoma of 154-155
 Torkildsen procedure in obstructive internal hydrocephalus, 200-207

Torticollis, spasmodic, rhizotomy for 354-355
 section of sternocleidomastoid muscle for 356-357
 Traction cervical with Vinke tongs, 72-75
 Trephine procedure for parasagittal cranial exploration, 304-305
 Trigeminal nerve, neuralgia of 10-33 See also *Neuralgia, trigeminal*
 sensory root of operation on for trigeminal neuralgia, 28-33
 Tumors, cerebral, 80-155
 Turkel bone biopsy of skull, 512-513

U

Ulnar nerve, exposure in arm 414-415
 exposure at wrist and hand, 412-413
 transplantation at elbow 408-411

V

Varix, aneurysmal, of spinal cord 446-447
 Ventricle(s), procedures affecting, 188-211
 third anterior tumor of 188-189
 colloid cyst of 190-183
 Ventriculoatrial shunt with Holter valve, in hydrocephalus, 208-211
 Ventriculocisternal drainage in obstructive internal hydrocephalus, 200-207
 Ventriculography procedure for 488-493
 Ventriculostomy anterior third, for hydrocephalus, 194-199
 Verruis, hemangioma of 150-151
 Vertebral artery fusiform aneurysm of 178-179
 Vinke tongs, cervical traction with, 72-75

W

Wen of scalp, removal, 2-3
 Wrist, exposure of median nerve at, 404-405
 exposure of ulnar nerve at, 412-413
 median nerve compression at, 406-407
 Wryneck, rhizotomy for 354-355
 section of sternocleidomastoid muscle for 356-357
